Abstract: The Qingkuangshan Ni-Cu-PGE deposit, located in the Xiaoguanhe region of Huili County, Sichuan Province, is one of several Ni-Cu-PGE deposits in the Emeishan Large Igneous Province (ELIP). The ore-bearing intrusion is a mafic-ultramafic body. This paper reports major elements, trace elements and platinum-group elements in different types of rocks and sulfide-mineralized samples in the intrusion. These data are used to evaluate the source mantle characteristics, the degree of mantle partial melting, the composition of parental magma and the ore-forming processes. The results show that Qingkuangshan intrusion is part of the ELIP. The rocks have trace element ratios similar to the coeval Emeishan basalts. The primitive mantle-normalized patterns of Ni-Cu-PGE have positive slopes, and the ratios of Pd/Ir are lower than 22. The PGE compositions of sulfide ores and associated rocks are characterized by Ru depletion. The PGE contents in bulk sulfides are slightly depleted relative to Ni and Cu, which is similar to the Yangliuping Ni-Cu-PGE deposit. The composition of the parental magma for the intrusion is estimated to contain about 14.65 wt% MgO, 48.66 wt% SiO₂ and 15.48 wt% FeO_t, and the degree of mantle partial melting is estimated to be about 20%. In comparison with other typical Ni-Cu-PGE deposits in the ELIP, the Qingkuangshan Ni-Cu-PGE deposit has lower PGE contents than the Jinbaoshan PGE deposit, but has higher PGE contents than the Limahe and Baimazhai Ni-Cu deposit, and has similar PGE contents to the Yangliuping Ni-Cu-PGE deposit. The moderate PGE depletions in the bulk sulfide of the Qingkuangshan deposit suggest that the parental magma of the host intrusion may have undergone minor sulfide segregation at depth. The mixing calculations suggests that an average of 10% crustal contamination in the magma, which may have been the main cause of sulfide saturation in the magma. We propose that sulfide segregation from a moderately PGE depleted magma took place prior to magma emplacement at Qingkuangshan, that small amounts of immiscible sulfide droplets and olivine and chromite crystals were suspended in the ascending magma, and that the suspended materials settled down when the magma passed through the Qingkuangshan conduit. The Qingkuangshan sulfide-bearing intrusion is interpreted to a feeder of Emeishan flood basalts in the region.

Key words: Magmatic sulfide deposit, mafic-ultramafic intrusion, PGE, Qingkuangshan, Emeishan Large Igneous Province

1 Introduction

The Qingkuangshan Ni-Cu-PGE deposit is a sulfide-rich Ni-Cu-PGE deposit. It is located in the Xiaoguanhe region of Huili County, Sichuan Province, where many magmatic

sulfide deposits associated with the Emeishan Large Igneous Province (ELIP) occur. There are more than 20 mineralized intrusions in this region, such as the Limahe, Qingkuangshan, Yanghewu, Hetaoshu intrusions (Fig. 1). Based on previous study, these deposits are products of magmatic activity of the ELIP (Yao, 1986; Xu et al., 2001; Zhou et al., 2002; Song et al., 2005, 2006, 2008, 2009;

* Corresponding author. E-mail: taoyan@vip.gyig.ac.cn

Guan et al., 2010).

In the ELIP, magmatic Ni-Cu-PGE deposits associated with mafic-ultramafic intrusions have highly variable sulfide compositions from PGE-rich to PGE-poor (Song et al., 2008), and they can be divided into three types: (1) sulfide-poor PGE deposits, of which the best example is the Jinbaoshan Pt-Pd deposit (Tao et al., 2007a); (2) sulfide-rich Ni-Cu deposit, such as the Baimazhai and Limahe nickel deposits (Tao et al., 2004, 2007b; Wang CY et al., 2005, 2006); (3) sulfide-rich Ni-Cu-PGE deposits such as the Yangliuping and Qingkuangshan Ni-Cu-PGE deposits (Wang et al., 2001; Song et al., 2003, 2008, 2009). The Qingkuangshan Ni-Cu-PGE deposit is same as the Yangliuping Ni-Cu-PGE deposit, which is characterized by enrichments of Cu, Ni and PGE (Song et al., 2008, 2009). All these deposits are related to the ELIP, what caused the variation in sulfide ore compositions? Is it due to the different primary magma or different magma evolution? To answer these questions it is important to understand the relationship between the Cu-Ni-PGE mineralization and the evolution of the ELIP. The Qingkuangshan deposit is a typical Ni-Cu-PGE deposit in the region, it has been poorly studied now, and a further study of the deposit is much needed (Song et al., 2008). This paper reports the results of a integrated study including major elements, trace elements and platinum-group elements in various rock types and mineralized samples from the intrusion. The results are used to evaluate the relationship between the ore-bearing intrusion and the coeval Emeishan flood basalts. And the nature and origin of the primary magma as well as the ore-forming mechanism are discussed. Our results shed new lights on the controls on the formation of magmatic sulfide deposits in the ELIP and are useful for regional mineral exploration.

2 Geological Background

The Qingkuangshan Ni-Cu-PGE deposit is located in the Xiaoguanhe region of Huili County. It is approximately 75 km from Huili City (Fig. 1). The ore-bearing intrusion outcrops in the inner zone of the ELIP where low-Ti basalts are abundant.

Geologically, this deposit is situated in the middle of Kang-Dian massif and is controlled by the Hekou duplex anticline and An-Ning River-Yimen deep fault. In the mining area, there are three groups of faults: SN striking (F_1), NE striking (F_2) and NW striking (F_3). The ore-controlling structure is the SN fault (F_1), which controls the occurrence of the Qingkuangshan intrusion and associated ore body. The NE fault (F_2) and NW fault (F_3) formed later. Due to the effect of NE fault (F_2), the occurrence of SN fault (F_1) was slightly changed: at 1750 level, the fault

strikes 10° – 20° , dips to SW with the angle of 70° – 88° ; at 1650 level, the fault strikes south-north, dips to SW with the angle of 64° – 71° . Moreover, NW fault (F_3) cutted NE fault (F_2), therefore, the displacement of NE fault (F_2) has happened (Fig. 2).

In the ore district, the main strata are the Middle Proterozoic Hekou Group. The occurrence of the strata is usually $NW10^{\circ}$ – 40° , and the dipping angle is 50° – 80° . The main exposed formation is mica schists, with minor lenticular dolomitic marble and carbonaceous slates. From the bottom to top, the strata can be divided into garnet mica schist, mica-schists with quartz-hornstone, mica-schists with dolomitic marble, siliceous slate, quartzite, and black carbonaceous phyllite.

The ore-bearing intrusion intruded the Hekou Group along with south-north fracture. It is an approximately N-S-trending and westward dipping dyke-like body, about 200 m long and 20 to 50 m wide, and the dip angle of this intrusion is almost vertical. The ore-bearing intrusion has a funnel shape in cross section, gradually pinching out downward. The differentiation of the ore-bearing intrusion is significant, especially in the upper parts of intrusion. From the center to both sides, the ore-bearing intrusion is composed of peridotites, olivine pyroxenite (pyroxene peridotite) and gabbro. The ore-bearing intrusion is dominated by peridotites, that makes up about half of all facies.

The ore body is mainly hosted in ultramafic rocks (including peridotite, olivine pyroxenite and pyroxene peridotite), and is concordant with the hosted rocks. It occurs as an approximately N-S-trending len, pinching out in the sides of II and III sections at the surface. It has a tadpole-looking shape in horizontal plane, 150–200 m long with a dipping angle of 60° – 88° . It has a funnel shape in cross section, extending for about 150–180m vertically. At depth, the ore body was cut by the NE fault (F_2) to form offset of mineralization. Below the offset fault, the mineralization is mainly uneconomic with economical mineral resource; above the offset fault, the mineralization is mainly economic and forms a funnel-shaped ore body. In different parts of this ore body dipping changes from about 88° in the west to about 50° in the east (Fig. 2). The mineralization is dominated by sparsely disseminated sulfides to densely disseminated sulfides with minor massive sulfide ores (Fig. 3f, g, h). The densely disseminated ores are mainly present in the peridotite at the bottom part of intrusion. With the increasing pyroxene abundance, the grades of the ores decrease. Sparsely disseminated ores often occur above densely disseminated ores; massive ores are mainly controlled by faults and fractures to form saclike bodies. Small massive ores also occur in the central portion of some densely disseminated

ores (The original 401 Geological Brigade of Sichuan Bureau of Geology and Mineral Resources, 1960^①; Yao, 1986).

3 Petrographic Characteristics

Samples were collected from tunnel, including all kinds of rocks and ores. The rocks are made up of ultramafic rocks and mafic rocks including olivine pyroxenite,

pyroxene peridotite, plagioclase-bearing pyroxene peridotite, pyroxenite and gabbro; and the ores include sparsely disseminated ore, densely disseminated ore and minor massive ore (Fig. 3f, g, h).

The ore-bearing olivine pyroxenite and pyroxene peridotite have the character of dull black medium-fine grained texture as well as massive texture. The major rock-forming minerals in these rocks are basically the same, but the abundances of olivine and pyroxene in olivine

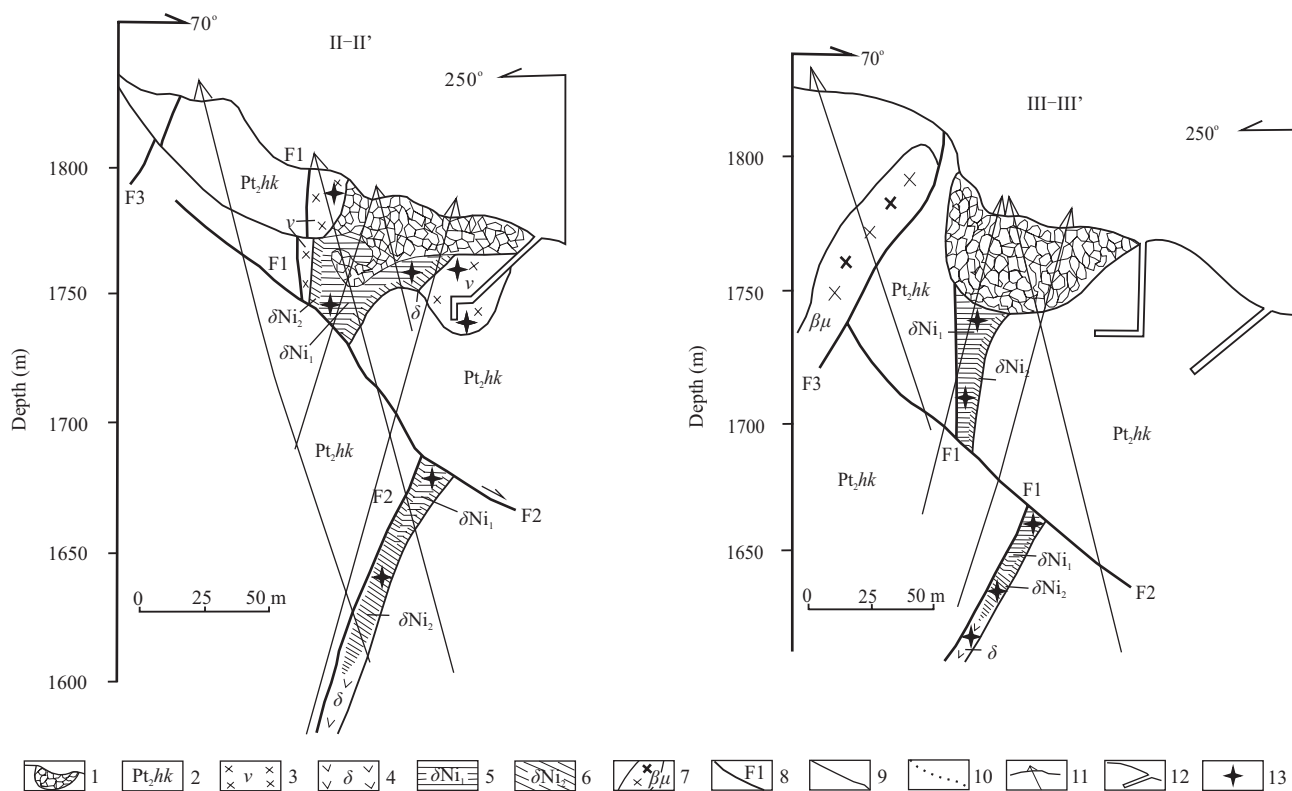

Fig. 2. The cross-section of the Qingkuangshan Ni-Cu-PGE deposit (modified from Yao, 1986).

1, Goaf; 2, metamorphic rock series of the Hekou Group; 3, gabbro; 4, peridotite; 5, economical mineral resource of peridotite; 6, uneconomical mineral resource of peridotite; 7, diabase; 8, fault and its number; 9, geological boundary; 10, transitional geological boundary; 11, drill hole; 12, tunnel; 13, sampling position.

pyroxenite and pyroxene peridotite are different, the major rock-forming minerals that mainly consist of olivine (about 20%–60%) and pyroxene (about 70%–30%) with minor plagioclase (about 2%–3%); and the abundance of plagioclase in the plagioclase-bearing pyroxene peridotite is slightly higher (about 5%). The grain sizes of olivine are highly variable. They have been partially serpentinized but peritectic texture is still preserved (Fig. 3a). Pyroxenes are dominated by clinopyroxene plus minor orthopyroxene. Plagioclases has a labradorite composition. It commonly exhibits tabular twins (Fig. 3b). In the ultramafic rocks, metallic minerals are dominated by pyrrhotite, pentlandite and chalcopyrite. Minor pyrite, chromite and magnetite are also present. They occur as disseminated assemblages, as small veins in the fractures of silicates and rarely as larger sulfide patches (Fig. 3c, d). Because of different crystallization temperatures different minerals crystallized at different times. Based on textural observations the metallic minerals are inferred to have crystallized in the following order: chromite, pyrrhotite, pentlandite, magnetite, pyrite and chalcopyrite.

Pyroxenites have the character of dull black, coarse to fine grained texture, as well as massive texture. Pyroxene crystals are euhedral or subhedral. In pyroxenites, the contents of pyroxene can reach up to 80% plus minor

olivine, amphibole and plagioclase. The rocks are mostly not sulfide-mineralized or contain rare sulfides.

Gabbros have the character of dark grey to grey, medium to fine grained texture, as well as massive texture. Pyroxene crystals are subhedral to xenomorphic. Sulfides are rare commonly. The main rock forming minerals are pyroxene (about 50%) and plagioclase (about 30%) with minor biotite (about 5%) and amphibole, accessory minerals are apatite, ilmenite, titanite and so on.

4 Samples and Analytical Methods

The compositions of major rock-forming minerals were analyzed using an EPMA-1600 electron microprobe in the State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China. The diameter of electron-beam, accelerating voltage and beam current were 22 μm , 25 kV, 10 nA, respectively. The sulfide-bearing rocks and sulfide-barren rocks were analyzed for major, trace and rare earth element compositions. The samples analyzed include olivine pyroxenite, pyroxene peridotite, plagioclase-bearing pyroxene peridotite, pyroxenite and gabbro. The analyses of major elements, trace elements and rare earth elements were done by the ALS Chemex. The samples for

Fig. 3. Back-scattered electron images and microphotographs of some samples in Qingkuangshan Ore-bearing rocks and the photographs of main types of ore

a, Olivine (Ol) enclosed within clinopyroxene (Cpx) and has the crystal stack structure; b, between the olivine and the clinopyroxene distributes the few plagioclase feldspar which has double crystal phenomena; c, magnetite (Mt) occurs as micro-scale veinlets along the crack of olivine; d, few big pellet chromite (Chr); e, olivine websterite; f, sparsely disseminated ore; g, densely disseminated ore; h, massive ore.

major elements analysis were prepared using lithium metaborate or lithium tetraborate menstruum and analyzed by ICP-AES. The detection limits are about 0.01 wt%. The samples for trace and rare earth element analysis were prepared using lithium metaborate and analyzed by ICP-MS. The concentrations of PGEs in the samples were determined in the National Research Centre for Geoanalysis in Beijing by ICP-MS. The analytical procedures of PGEs are the same as in Zhang et al. (2005b), and detection limits are Os 0.007 ppb, Ir 0.013 ppb, Ru 0.02 ppb, Rh 0.001 ppb, Pt 0.026 ppb and Pd 0.06 ppb.

5 Geochemical Characteristics

5.1 Mineral chemistry

Table 1 lists the representative compositions for major rock-forming minerals in the ultramafic rocks. Generally, the olivines have a great change in the particles size (about 0.2–0.5 mm) and are enclosed in pyroxenes, most of them are fresh, and only small fractions have the serpentinized phenomena. Olivine has a chrysolite composition (Fo=78–85). Pyroxenes crystals in the ultramafic rocks are mainly diopside with minor bronzite, and the bronzite generally grow in diopside.

The nickel content in olivine of the Qingkuangshan intrusion is 1000–1500 ppm (Table 1). The nickel content of the parental magma is estimated to be 100–150 ppm. Olivine crystals of the Qingkuangshan intrusion exhibit a positive Ni-Fo correlation, which suggest that they formed by fractional crystallization of a single parental magma. Modeling shows that 9%–10% fractional crystallization of picritic magma can explain the observed olivine compositions (Fig. 4). In comparison with olivine from the Jinbaoshan Pt-Pd deposit (nickel content 1500–2000 ppm), the nickel contents of olivine from the Qingkuangshan intrusion is lower, which may be due to early sulfide segregation in the parental magma of the Qingkuangshan intrusion.

5.2 Major elements

The analytical results of the major elements in whole rocks are listed in Table 2. The SiO₂ and MgO contents of mafic-ultramafic rocks are between 33.5 wt%–49.9 wt% and 7.13 wt%–27.2 wt% respectively. The CaO/Al₂O₃ varies between 0.88 and 4.40. Generally, the mafic-ultramafic rocks are high in MgO but low in Al₂O₃, P₂O₅, K₂O and Na₂O. The m/f ratios of these rocks are between 0.66 and 4.92, within the range for ferric mafic-ultramafic rocks. Due to variable hydrothermal alteration and sulphide contents, the LOI values are highly variable.

The Harker diagrams (Fig. 5) show that, due to variable post-magmatic hydrothermal alteration, as the contents of

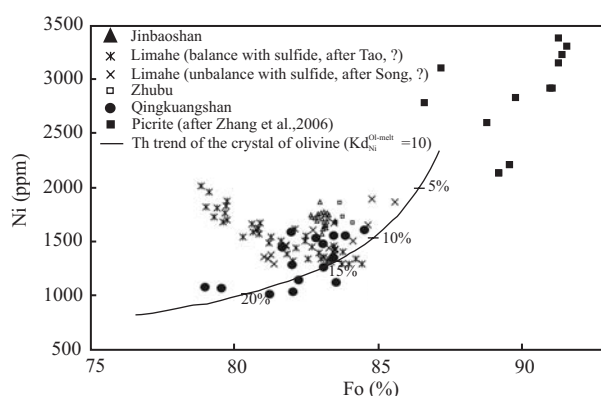

Fig. 4. Plots of Fo versus Ni contents for olivine in the ultramafic rocks of the Qingkuangshan intrusion.

Picrites from Zhang et al., 2006; Jinbaoshan from Tao et al., 2007a; Zhubu from Tao (unpublished data); curve on the figures represent the number of olivine crystals.

MgO decrease, the contents of Al₂O₃, K₂O, Na₂O and TiO₂ in the samples increase. SiO₂ contents increase with decreasing MgO content but then decreased. The P₂O₅ and FeO_t contents show no clear trends. Generally, the compositional variations in the Qingkuangshan mafic-ultramafic rocks are similar to that of the coeval Emeishan picrites.

5.3 The characteristics of rare earth and trace element compositions

The concentrations and ratios of REE and trace elements are listed in Table 3.

5.3.1 Rare earth elements

The total REE contents of the mafic-ultramafic rocks are rather low as compared to the Emeishan picrites (except the high contents of QK0818 and QK0821), as a whole, the mafic rocks have higher total REE contents than the ultramafic rocks of the intrusion. The mafic-ultramafic rocks have 1.59–2.79 (La/Sm)_N, 7.85–12.19 (La/Yb)_N, 6.80–11.21 (Ce/Yb)_N, 5.93–8.99 (Σω(Ce)/Σω(Y)). The chondrite-normalized REE patterns of the mafic-ultramafic rocks are similar to that of OIB such as LREE enrichments relative to HREE. However the contents of REE in the Qingkuangshan mafic-ultramafic rocks are lower than those in OIB (Fig. 6a). Overall, the mafic-ultramafic rocks are characterized by normal to negative anomalies of δCe and δEu values ranging from 0.92 to 1.04 and from 0.89 to 1.12, respectively. The Eu negative anomalies may have been in part due to plagioclase fractional crystallization or post-magmatic hydrothermal alteration (Zhong et al., 2004). Alternatively contamination with crustal material may have also caused the Eu negative anomalies.

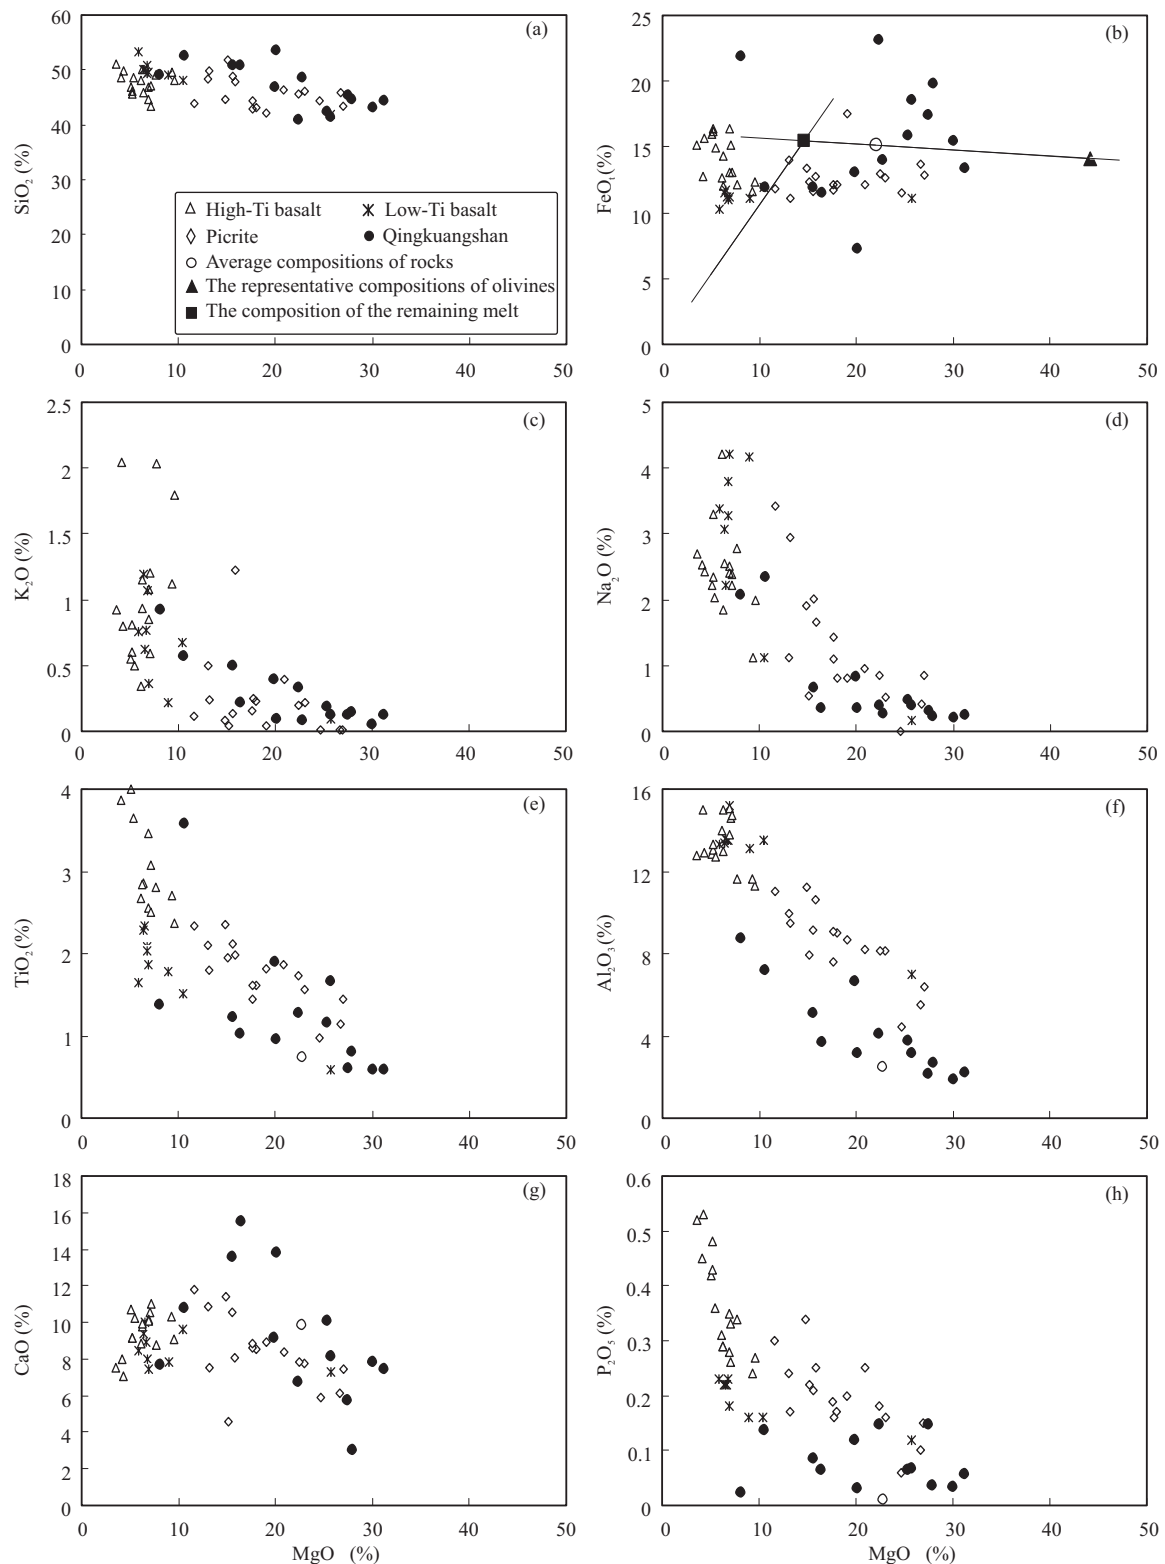

Fig. 5. Diagram of MgO versus major oxides of the Qingkuangshan intrusion. Picrites from Zhang et al., 2006; high Ti basalts and low Ti basalts from Xu et al., 2001.

5.3.2 Trace elements

The primitive mantle-normalized trace element patterns of the mafic-ultramafic rocks are similar to that of OIB except for slight depletion of Ba, Nb, Ta, Sr and Ti, and

enrichments of Th and U (Fig. 6b). The depletions of Nb, Ta, Ti and Zr may have been due to crustal assimilation which is present in the coeval basalts (Xu et al., 2001; Xiao et al., 2004; Zhang et al., 2006; Tao et al., 2007b). The

Table 3 Trace element concentrations (ppm) and eigenvalues of the Qingkuangshan mafic-ultramafic rocks.

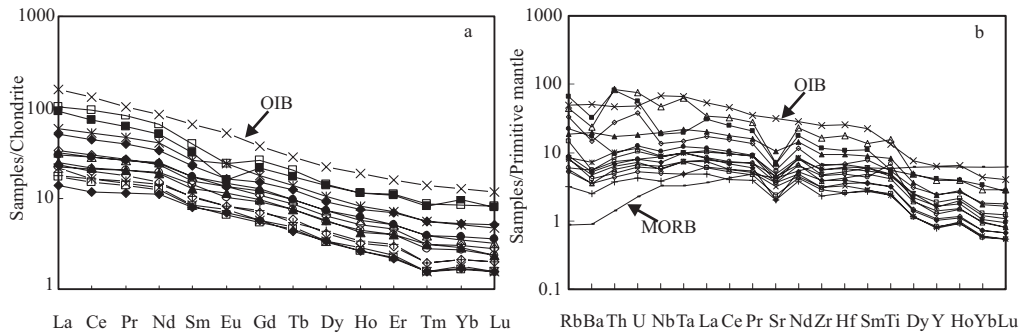

Fig. 6. Chondrite-normalized REE patterns and primitive mantle-normalized trace element patterns for the Qingkuangshan mafic-ultramafic rocks.

CI, OIB, MORB and Primitive mantle values after Sun and MacDonough, 1989.

subparallel primitive mantle-normalized trace element patterns of the mafic-ultramafic rocks suggest that these rocks are related to a single magma.

5.4 Ni, Cu, and platinum-group elements

The concentrations of PGE, Cu and Ni in whole rock samples are listed in Table 4. The primitive mantle-normalized Ni-PGE-Cu patterns of the sulfide-bearing samples in recalculated 100% sulfide and sulfide-barren samples are illustrated in Fig. 7. These plots show that all samples from the Qingkuangshan intrusion are enriched in PPGE (Pt, Pd) relative to IPGE (Os, Ir, Ru and Rh), Ru depletion is present in the samples.

Previous studies have showed that the primitive mantle-normalized PGE patterns of mantle xenoliths, Alps-type

peridotites and komatiites are nearly flat and have lower Pd/Ir ratios. The enrichments of PPGE relative to IPGE in Qingkuangshan samples may have been related to mantle partial melting, furthermore, variation in mantle source compositions and mantle partial melting can also contribute to the fractionation of PGE in mantle-derived magma (Tao et al., 2004). The Qingkuangshan intrusion is thought to have derived from magma generated in an OIB-type mantle characterized by PPGE enrichments and high Pd/Ir ratios ranging from 10 to 30. In the plot of Ni/Cu-Pd/Ir (Fig. 8), the Qingkuangshan samples mainly fall within the field of high-Mg basalt or below it, suggesting that the primary magma of the Qingkuangshan intrusion formed by high degree of mantle partial melting.

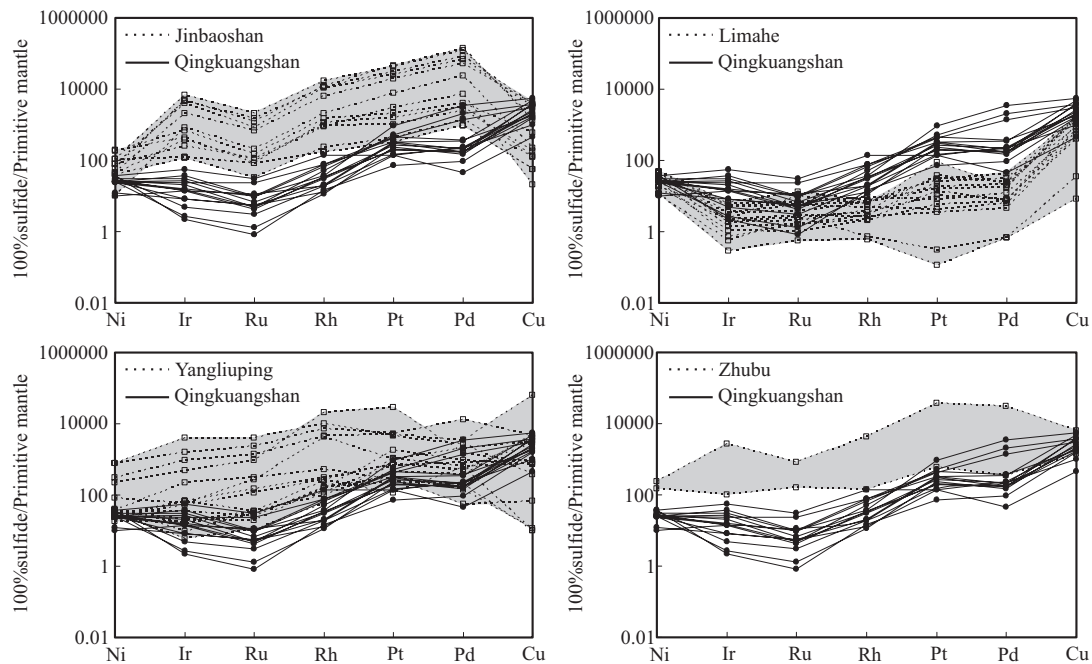

Fig. 7. Primitive mantle-normalized Ni-PGE-Cu patterns of sulfide ores on a 100% sulfide basis and sulfide-barren rocks of the Qingkuangshan Ni-Cu-PGE magmatic sulfide deposit.

Cu, Ni, PGE of primitive mantle values after Barnes and Maier, 1999; Jinbaoshan and Limahe from Tao et al., 2007a, 2008; Zhubu from Zhu et al., 2007; Yangliuping from Song et al., 2003, 2008.

Fig. 8. Ni/Cu against Pd/Ir ratios diagram for the Qingkuangshan intrusion (Fields from Barnes and Lightfoot, 2005; Emeishan basalts from Zhong et al., 2006).

6 Discussion

6.1 Parental magma compositions

Previous studies showed that the ratios of chalcophile elements (Ni, Cu and PGE) are rarely affected by crustal contamination and mainly reflect the composition of parental magma (e.g., Keays, 1995). Ultramafic magmas usually give rise to Ni-dominated sulfide deposits with Ni/Cu ratios higher than 7, such as the komatiite-associated Ni deposits in Kambalda, Western Australia (Ni/Cu=13.5) (Leshner et al., 1984). Mafic magmas commonly produce Ni-Cu-(PGE) sulfide deposits with Ni/Cu usually less than 2 (Naldrett, 2004), such as the Noril'sk Ni-Cu-PGE deposits, Siberia (Ni/Cu=0.5–1.06) and the Voisey's Bay Ni-Cu-Co deposit, Canada (Ni/Cu=1.87). As shown in Table 4, the Qingkuangshan samples have an average Ni/Cu ratio of 1.03, with a small range of 0.48 to 1.85. Therefore, the Qingkuangshan intrusion may have derived from a mafic magma.

Under equilibrium conditions, olivine composition reflects the composition of the magma from which the olivine crystallized. Thus, using Mg-Fe exchange coefficient ($K_d = [(FeO/MgO)_{Ol}/(FeO/MgO)_{magma}]_{molar} = 0.3-0.34$) (Roder and Emslie, 1970; Hanson and Langmuir, 1978; Ulmer, 1989; Thompson and Gibson, 2000) and the composition of most Mg-rich olivine in the rocks (Chai and Naldrett, 1992), we can estimate the parental magma composition. The most Mg-rich olivine in the Qingkuangshan intrusion is Fo=84.9, which corresponds to an MgO/(MgO+FeO) value of 0.946 for the liquid in equilibrium with olivine, based on a distribution coefficient of $K_d=0.3$ (Roeder and Emslie, 1970). We then estimated other oxide contents in the magma based on of the

correlation between MgO and other oxides (Fig. 5b). The average estimated values are 14.65% MgO, 48.66% SiO₂, 15.48% FeO, 0.93% Na₂O, 0.42% K₂O and 1.80% TiO₂.

If values for the most Mg-rich olivine compositions from a sample plot on an olivine-liquid equilibrium curve at approximately the same FeO content as present in the bulk rock, the MgO content of the rock is close to that of the liquid from which the olivine crystallized. The calculated MgO/(MgO+FeO) value is much lower than the MgO/(MgO+FeO) values of the Qingkuangshan intrusive rocks. In Fig. 9 olivine Mg-number is plotted vs. whole-rock MgO content, the compositions of the most Mg-rich olivine plot below the liquid-olivine mixing line of closed system, indicating excess (cumulus) olivine in the samples (Zhang and Wang, 2003; Chai et al., 2007). Due to re-equilibration with trapped silicate liquid before complete solidification, final olivine is less Mg-rich than original cumulus crystals. Therefore, the estimated MgO content for the parental magma is likely less than the true value (Wu et al., 2004).

In terms of the major elemental discrimination of Hawaiian picrites in primary magma (MgO=16%–21%) (Hirschmann and Ghiorso, 1994; Norman and Garcia, 1999; Herzberg and O'Hara, 2002), the estimated parental magma for Qingkuangshan area is low-Ti tholeiite with the character of high-Mg (Fodor, 1990; Xu et al., 2001), far from high-Ti basalt with the character of low-Mg from ELIP (Xiong et al., 1984).

Figure 10 compares the Qingkuangshan intrusion with associated volcanic rocks using incompatible trace elements such as La, Sm, Gd, Yb and Y, and their ratios such as La/Sm, Gd/Yb, and Ti₂O/Y. Samples from the Qingkuangshan intrusion, low-Ti basalts and picrites of the ELIP have similar trends, which are significantly different from coeval high-Ti basalts. The results show that the parental magmas of the Qingkuangshan mafic-ultramafic intrusion are similar to of the coeval low-Ti basalts reported previously by Xiao et al. (2004), suggesting that the Qingkuangshan mafic-ultramafic intrusion was produced

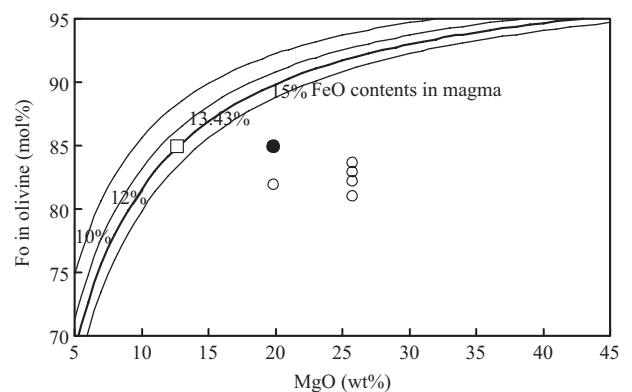

Fig. 9. Diagram of MgO-Fo-FeO.

●, the highest Fo values of olivine; ○, the other high Fo values of olivine; □, primitive magma.

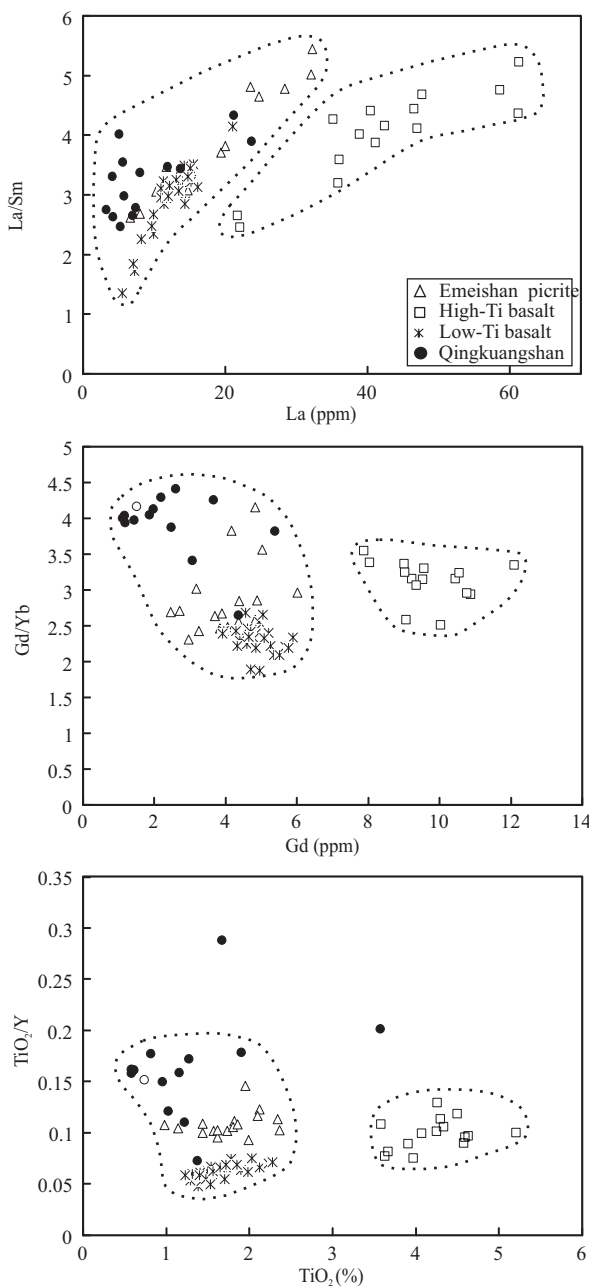

Fig. 10. Plots of trace elements on La/Sm-La, Gd/Yb-Gd and $\text{TiO}_2/\text{Y}-\text{TiO}_2$ (Picrites from Zhang et al., 2006; high Ti basalts and low Ti basalts from Xiao et al., 2004)

by higher degree of mantle partial melting.

6.2 Petrogenesis

Because Yb is compatible in garnet but not in clinopyroxene, Sm/Yb ratio can be used to constrain mantle source mineralogy of alkaline magmas (Aldanmaz et al., 2000). Fig. 11 is the plot of garnet-dependent Sm/Yb ratio vs. Sm. It can be seen that the Qingkuangshan mafic-ultramafic rocks have high Sm/Yb ratios, consistent with the products of magma derived from a mantle garnet-lherzolite. This is supported by

high $(\text{Gd}/\text{Yb})_{\text{pm}}$ ratios (2.2–3.6) of the samples. Magma derived from a garnet-stable source mantle is expected to have high $(\text{Gd}/\text{Yb})_{\text{pm}}$ ratios because the garnet-melt partition coefficients for HREE are much higher than those for LREE.

On the basis of some correlatively researches for source characters of ELIP in recent years (e.g. Xu et al., 2004; Zhang et al., 2005a; Zhou et al., 2006; Xu et al., 2007), and the aforementioned discussion of source characters for Qingkuangshan intrusion, the magmatic source of Qingkuangshan intrusion was being analogous to oceanic island basalts sources. And based on this condition, using the content of REE in primary magma, we can estimate the degree of mantle partial melting by way of that:

$$F = C_i^{\text{source}} / C_i^{\text{magma}}$$

F—the degree of partial melting of the mantle,

i—the strong incompatible element i,

C_i^{source} —the content of strong incompatible element in source region,

C_i^{magma} —the content of strong incompatible element in primary magma,

The approach to estimate the content of strong incompatible elements in primary magma (e.g. REE) is to use the method of the Li. (1986)^②

$$\text{REE}_i^{\text{melt}} = \text{REE}_i^{\text{rock}} / (1 - f + K_i^{\text{Ol-melt}} \times f),$$

i—the rare earth element (REE),

$\text{REE}_i^{\text{melt}}$ —the content of REE in primary magma,

$\text{REE}_i^{\text{rock}}$ —the content of REE in rocks,

$K_i^{\text{Ol-melt}}$ —the distribution coefficient of REE between olivine and melt (after Bedard, 1999),

f—the weight percentage of olivine in their coexistence melt (f=0.415). The method of estimating the weight percentage of olivine is the principle of mass balance. We absorb the way of Tao et al. (2002) to estimate the weight percentage of olivine in their coexistence melt.

The estimated results of the degree of partial melting for the primary magma of the Qingkuangshan intrusion are

Fig. 11. Plot of Sm-Sm/Yb showing melt curves for Qingkuangshan intrusion (after Aldanmaz et al., 2000).

listed in Table 5. According to the contents of La and Ce elements in Qingkuangshan mafic-ultramafic intrusion, the corresponding degrees of partial melting for the primary magma are respective 23.8% and 22.6%. Considering the influences of crustal assimilation, the calculated value is high than the true value, it is roughly estimated that about 20%. That high degree of partial melting for the primary magma corresponding to lower Pd/Ir ratio (about 22) (Chu et al., 2001).

6.3 Crustal contamination

$(\text{Nb}/\text{Th})_{\text{pm}}$ is best used to indicate the extent of Nb anomaly and $(\text{Th}/\text{Yb})_{\text{pm}}$ is a sensitive indicator of crustal contamination, so, the degree of crustal contamination of the magmas can be estimated using $(\text{Nb}/\text{Th})_{\text{pm}}$ and $(\text{Th}/\text{Yb})_{\text{pm}}$ ratios where the rock values have been normalized to the relevant trace element content of the primitive mantle (Zhou et al., 2008; Wang, 2008).

In Fig. 12, the $(\text{Nb}/\text{Th})_{\text{pm}}$ vs $(\text{Th}/\text{Yb})_{\text{pm}}$ diagram, we assume that these mafic-ultramafic rocks are formed from a mixture of different proportions of mantle-derived magma and crustal contaminant. For the mantle-derived end member, we used two compositions, one being N-MORB (Sun and McDonough, 1989) and the other being the most primitive and least contaminated picrites of the west Emeishan flood basalt province. For the crustal end member, owing to lack of systematic analytical data of the upper crust sediments for this region, we used the average compositions of the upper crust and lower crust (Taylor and McLennan, 1985). Compared to N-MORB, the Qingkuangshan rocks have lower $(\text{Nb}/\text{Th})_{\text{pm}}$ but higher $(\text{Th}/\text{Yb})_{\text{pm}}$ ratios, consistent with a high degree of crustal contamination. And compared to the upper crust and lower crust or the lithosphere (Taylor and McLennan, 1985), the contents of Th element have a large range of variation from 0.4 ppm to 7.0 ppm which have some similarities with the former. The results of the comparison showed that the Qingkuangshan intrusion has underwent the contamination by little lithospheric or crustal before the formation of the rocks. The simulation results show that, using N-MORB as the mantle-derived end member do not correspond with the evolutionary trend of Qingkuangshan rocks, whereas the use of the average composition of the Emeishan picrites as the mantle-derived gives a good fit, and the degree of crustal contamination of the Qingkuangshan rocks varied from 3% to 12% by the upper crust.

6.4 Sulfur saturation and sulfide segregation

Keays pointed out whether the magmas had reached sulfide saturation was the crucial factor for the formation of the sulfide magmatic deposit. Experimental and theoretical studies suggest that Pd can be strongly concentrated in

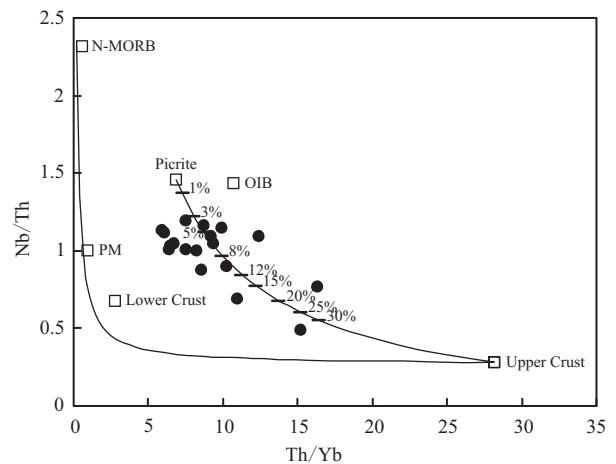

Fig. 12 $(\text{Th}/\text{Yb})_{\text{pm}}$ vs $(\text{Nb}/\text{Th})_{\text{pm}}$ diagram showing the degrees of crustal contamination.

Primitive mantle, OIB and MORB after Sun and McDonough (1989); upper and lower crust after Taylor, S.R and McLennan, S.M (1985); picrites from Zhang et al., 2006; curve on the figures represent the degrees of crustal contamination; partial data from mining companies' material.

sulfide, owing to the much larger sulfide liquid-silicate liquid partition coefficient for Pd (17000) relative to Cu (~1383), therefore, Cu/Pd ratio is an effective tool to evaluate sulfide saturation in magmas (Barnes and Maier, 1999). If the magma was S-unsaturated, Cu and Pd behave as incompatible elements, and therefore the Cu/Pd ratios of a primary magma should be similar to those observed for the mantle (about 6300) (Barnes et al., 1988); but in sulfide unsaturated magma, the Cu/Pd ratios of a primary magma should be much greater than 6300.

Almost all the samples from Qingkuangshan intrusion are characterized by Cu/Pd ratios higher than 6300, this may be due to the fact that sources of these basalts retained residual sulfides during melting or sulfide saturation had occurred in the early stage of magma evolution. The above discussion has shown that, because of the relatively large degree of partial melting of the mantle and the phenomenon of moderate PGE depletion in ores, the high Cu/Pd ratios for almost all the samples are unlikely due to retention of sulfides in the mantle. Therefore, the above analysis and evidence indicate that, during the magma ascent, the parental magmas had reached sulfide saturation and caused sulfide segregation, and then led to the formation of weakly PGE depleted magma.

From the Pd-Cu/Pd diagram (Fig. 13), we can see that different types of Ni-Cu-PGE magmatic sulfide deposit in Emeishan Large Igneous Province have different distribution. The Limahe and Baimazhai Ni-Cu deposits are characterized by strong depletion in PGE relative to Ni and Cu, with lower Pd and high Cu/Pd ratios (greater than 200000); the Jinbaoshan Pt-Pd deposit is characterized by the enrichment of PGE, with higher Pd and low Cu/Pd

ratios (lower than 1000); and the Yangliuping and Zhubu deposits are characterized by intermediate Pd contents and Cu/Pd ratios. Song et al. (2008) pointed out that Yangliuping deposit was produced by extensive sulfide segregation from weakly PGE-depleted magmas, because of earlier sulfide removal. Samples from the Qingkuangshan, Yangliuping and Zhubu deposits have similar trends, which show that Qingkuangshan deposit was produced by extensive sulfide segregation from weakly PGE-depleted magmas.

In order to study the influence of sulfide segregation on Qingkuangshan intrusion, it is necessary to do the model calculation via the following equation of Campbell and Naldrett (1979): $C_i^{Sul} = C_i^{Sil} \times D_i^{Sul/Sil} \times (R+1)/(R+D_i^{Sul/Sil})$, where C_i^{Sul} and C_i^{Sil} represent the concentrations of element i in the sulfide melt and in the parental silicate magma, respectively; $D_i^{Sul/Sil}$ is the sulfide melt/silicate liquid partition coefficient of element i ; and R is the R-factor.

On the basis of the aforementioned discussion of magmatic origin for Qingkuangshan intrusion, we assume that the ELIP basaltic magmas had 15 ppb Pt, 22 ppb Pd, 1 ppb Ir, and 200 ppm Cu before reaching S-saturation, which represents the primary magma of the Qingkuangshan intrusion. The model calculation result (Fig. 13) indicates

that the parental magma had undergone a small amount of segregation sulfide lost (about 0.014%) in the early magma evolution, which led to the formation of moderately PGE depleted magma. Subsequently, the moderately PGE depleted magma underwent the further contamination and further sulfide segregation with R-factors ranging from 1000 to 6000, and then led to the formation of sulfide melts, which are roughly consistent with the contents of Pd, Ni and Cu of the pure sulfide melts of the Qingkuangshan PGE ores.

6.5 A diagenetic and metallogenic model

Studies showed that PGE contents in primary magma are strongly dependent on the composition of mantle-derived rocks, the degree and the mechanism of mantle partial melting. Keays (1995), Rehkämper et al. (1999) and Peach (1996) assume that the primitive mantle had 4 ppb Pd and 250 ppm S, if the degree of batch partial melting was about 20%, the content of Pd in melts can reach to the theoretically maximum value (about 20 ppb). So far, the search has not been reported of the content of Pd in primary magma more than 40 ppb. Hamlyn et al. (1985) had reported that the Boninites derived from the depleted mantle have very high content of Pd with the highest

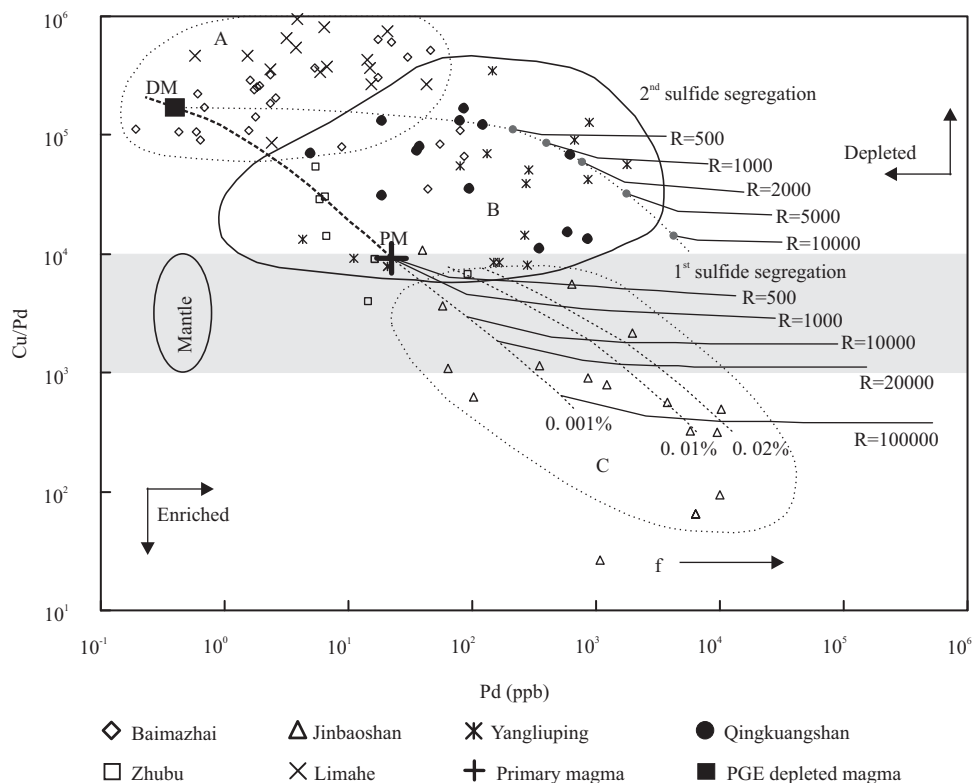

Fig. 13. Pd vs Cu/Pd diagram of typical Ni-Cu-PGE magmatic sulfide deposits in Emeishan Large Igneous Province.

F, content of segregated sulfide; A, the distribution of Limahe and Baimazhai; B, the distribution of Yangliuping and Zhubu; C, the distribution of Jinbaoshan. Primitive mantle values after Sun and MacDonough, 1989; Limahe from Tao et al., 2008; Baimazhai from Wang CY et al., 2006; Zhubu from Zhu et al., 2007; Yangliuping from Song et al., 2008; Jinbaoshan from Tao et al., 2007a.

content of Pd (about 38 ppb), but the content of Pd in the melts derived from undepleted mantle is generally less than 30 ppb. The content of Pd in Qingkuangshan ore-bearing intrusion is far higher than 30 ppb with the average content of 100 ppb, which is well above the highest content of Pd in the melts derived from any mantle by partial melting, indicating that the primary magma of Qingkuangshan intrusion had undergone the accumulation of PGE before the formation of Qingkuangshan deposit.

The concentration of cumulate segregated sulfides in magma can trigger the accumulation of Cu, Ni and PGE; therefore, sulfide segregation is the main controlling factors on metallogenesis of magmatic sulphide deposit. The Qingkuangshan deposit is marked by relatively high PGE grades was thought to have been formed by accumulation of immiscible sulfide droplets from a large amount of magma in a sill-like conduit.

According to the calculation of sulfide segregation shown in Fig. 13, in the early stage of magma evolution, about 0.014% sulfide melt removal from the PGE rich primary magma would give rise to a moderately PGE depleted magma. Subsequently, owing to the contamination by crustal materials for moderately PGE depleted magma (ranging from 3% to 12%), the sulfides segregated from the moderately PGE depleted magma under R values ranging from 1000 to 6000, and mixed with olivine and chromite in the staging chamber to form mineral-laden mush. In a word, the intrusion was formed by concentration of cumulate minerals and segregated sulfides in magma conduit system.

7 Conclusions

(1) The major and trace elements variations of the Qingkuangshan mafic-ultramafic rocks show that the Qingkuangshan mafic-ultramafic rocks are products of magmatic activity in the ELIP, and their evolutionary trend is corresponding with Emeishan picrites; by estimating, the primary magma is picritic, with degree of about 20% mantle partial melting which is analogous to the source mantle of OIB;

(2) The segregation model analysis indicates that the ore-forming magma had undergone a small amount of segregation sulfide lost (about 0.014%) in the early magma evolution, which led to the formation of moderately PGE depleted magma, subsequently, the moderately PGE depleted magma underwent the further contamination and further strong sulfide segregation, and then led to the formation of sulfide ores with the character of moderate PGE-depletion;

(3) The model calculation suggests that the ore sulfides segregated from the moderately PGE depleted magma and mixed with olivine and chromite in the staging chamber to

form mineral-laden mush, subsequently, the intrusion was formed by concentration of cumulate minerals and segregated sulfides in magma conduit system.

Acknowledgements

The authors thank the two anonymous reviewers for their help in improving the quality of the manuscript. We are also very grateful to the National Research Center, the senior engineer of Zheng Wenqin and Dr Liu Shirong (Institute of Geochemistry, Chinese Academy of Sciences) for their kind help with the lab work. This study was financially supported by the Chinese Academy of Sciences (grant no. KZCX2-YW-Q04-06), the National Key Basic Research Program of China (grant no. 2009CB421005), and the National Science Foundation of China (grant no. 40973039).
