### ARTICLE INFO

*Keywords:*  Apatite Origins Rock types Deposit types Discrimination PLS-DA

## ABSTRACT

Partial least squares-discriminant analysis (PLS-DA) was used to construct the link between trace element contents of magmatic or hydrothermal apatite and deposit and rock types. Apatite with different origins is discriminated by characteristic chemical composition. In average, ore magmatic apatite has higher light REE and Th, and lower Sr than barren rock apatite, independent of deposit types. Hydrothermal apatite has lower La, Ce, Pr, and Nd contents than magmatic apatite, probably because fluids prefer migrating light rare earth element out of apatite. Hydrothermal apatite from iron oxide copper gold (IOCG) and iron oxide apatite (IOA) deposits is discriminated by high Mn and Sr relative to magmatic apatite, probably because these elements are fluid mobile. Barren magmatic apatite from granitoid-related deposits is well separated from ore magmatic apatite by higher Sr, Eu, Gd, Tb, Dy, and lower Mn contents, which are likely related to the relatively low degree of differentiation and high aluminum saturation index of parental magma.

Magmatic apatite from IOA deposits is discriminated by relatively high Nd, Sm, Gd, Tb, Dy, and low Mn and U contents, which are possibly related to the crystallization of Mn-compatible magnetite microlites and peraluminous magmas. Magmatic apatite from granitoid-related W deposits is relatively rich in Y, Sm, Gd, Tb, Dy, Ho, Er, Tm, Yb, and Lu. The relative enrichment of Sr in magmatic apatite from granitoid-related Cu-Pb-Zn and Pb-Zn deposits is likely due to less fractionation of Sr-compatible plagioclase. Melt of sediment component accounts for high Mn and Th in magmatic apatite from granitoid-related Mo deposits. Magmatic apatite from porphyry deposits is discriminated by relatively high V, Sr, and Eu contents. Magmatic apatite from porphyry Mo deposits has relatively high Pr, Nd, and Sm and low Sr contents compared to other types of porphyry deposits due to the more evolved magma. Hydrothermal apatite from IOA deposits is discriminated by high V and Sr, whereas those from IOCG deposits have high Sm, Eu, Gd, Tb, and U contents, because the lower temperature of IOCG cause precipitation of REE in Cl-rich fluid. Relatively low Gd and Tb in hydrothermal apatite from skarn deposits are possibly due to the crystallization of amphibole.

Apatite in carbonatite has high contents of trace elements possibly because high contents of Ca and P in melts cause high apatite-melt partition coefficients of trace elements. Apatite from sedimentary and metamorphic rocks is discriminated by relative enrichment of Sr and Eu. Compared to igneous rocks, apatite from sedimentary rocks has low REE contents, reflecting low REE budget in surface waters. Breakdown of some minerals to release and remobilize REE and U during metamorphism can interpret high heavy REE and U contents in apatite from highgrade metamorphic rocks relative to those from low- and medium-grade metamorphic rocks. The ability to discriminate apatite from different types of deposits and rocks indicates the application potential of apatite chemistry in mineral exploration. A flowchart was proposed to identify apatite with unknown origins.

#### **1. Introduction**

Apatite  $[Ca_{10}(PO_4)_6(F, Cl, OH)]$  is a ubiquitous mineral in igneous, metamorphic, and sedimentary rocks ([Bouzari et al., 2016; Webster and](#page-20-0) 

[Piccoli, 2015\)](#page-20-0), and it can also form by biomineralization [\(Elliott, 2002;](#page-20-0)  [Hughes and Rakovan, 2002; Piccoli and Candela, 2002\)](#page-20-0). Apatite can be stable in weathering and transport in the surface environment [\(Belou](#page-20-0)[sova et al., 2002; Mao et al., 2016\)](#page-20-0), which makes apatite become an

Available online 21 December 2022 Received 28 July 2022; Received in revised form 17 December 2022; Accepted 18 December 2022

<sup>0169-1368/© 2022</sup> The Author(s). Published by Elsevier B.V. This is an open access article under the CC BY-NC-ND license([http://creativecommons.org/licenses/by](http://creativecommons.org/licenses/by-nc-nd/4.0/) $nc\text{-}nd/4.0/$ ).

ideal indicator mineral. Early crystallized magmatic apatite is weakly affected by later alteration and metamorphism, and thus preserves the information of the parental magma ([Ayers and Watson, 1993; Watson](#page-20-0)  [and Green, 1981](#page-20-0)). The Mn content, Ce, and Eu anomalies in apatite are used to indicate the relative oxygen fugacity of the magmatic rock related to mineralization ([Cao et al., 2012; Pan et al., 2016; Sha and](#page-20-0)  [Chappell, 1999; Xing et al., 2021](#page-20-0)). In addition, the contents of major and trace elements in apatite can discriminate different types of rocks and deposits and evaluate the mineralization potential of the host rocks ([Belousova et al., 2002; Cao et al., 2012; Chappell and White, 1992;](#page-20-0)  [Jiang et al., 2018; Mao et al., 2016; O](#page-20-0)'Sullivan et al., 2020; Pan et al., [2016; Piccoli and Candela, 2002\)](#page-20-0).

As an important indicator mineral, numerous studies have been carried out for apatite origin discrimination. Contents of Na, Ca, Sr, Cr, and Ni,  $Fe^{3+}/Fe^{2+}$  ratio, REE patterns, and element ratios (e.g., La/Y, Sm/Nd) are used to discriminate apatite from different types of granite ([Chappell and White, 1992; Sha and Chappell, 1999\)](#page-20-0). Eu/Eu\* and Ce/ Ce\* of apatite is used to constrain the oxygen fugacity of the crystallization environment (Cao et al.,  $2012$ ). Based on the contents of Sr, Y, Mn, total REE, REE pattern and the Eu anomaly of apatite, [Belousova](#page-20-0)  [et al. \(2002\)](#page-20-0) used correlation and regression trees to classify different types of rocks. Machine learning methods such as principal component analysis, support vector machine, and decision tree algorithm are used to discriminate deposit types, and rock types and determine whether the rocks are mineralization-related [\(Mao et al., 2016; O](#page-21-0)'Sullivan et al., [2020\)](#page-21-0). These results provide a good basis for apatite origin discrimination.

In this study, LA-ICP-MS trace element data of apatite from the published literature were systematically collected. The large dataset was investigated by partial least squares-discriminant analysis (PLS-DA) to link apatite chemistry with their origins (i.e., magmatic versus hydrothermal, barren versus mineralization, different types of deposits and rocks). The factors controlling variations in the chemical composition of apatite were discussed. Some PLS-DA diagrams with good discrimination for deposit or rock types can be used to constrain the origin of apatite without known background information, which will be important for quick screening in mineral exploration.

## **2. Data preparation**

#### *2.1. Date source*

A total of 4298 data were collected from different types of deposits and rocks [\(Appendix 1\)](#page-0-0). These deposits and rocks hosting apatite are from different countries and areas: Australia, Brazil, Canada, Chile, China, Finland, France, Germany, Greece, Greenland, Iceland, Iran, Italy, Kazakhstan, New Zealand, Norway, Peru, Russia, Scotland, Sweden, Ukraine, USA, and Mid-Atlantic Ridge (Fig. 1, [Appendix 1\)](#page-0-0). We divide apatite into ore and barren magmatic apatite, hydrothermal apatite according to the mineralization potential of hosted rock, and the origin of hydrothermal or magmatic ([Appendix 2\)](#page-0-0). The number of magmatic apatite is 1801 and 101 for silicate rocks and carbonatite, respectively. Apatite data of sedimentary and metamorphic rocks are 108 and 360, respectively. The number of hydrothermal apatite from porphyry, IOA, skarn, IOCG, and orogenic Au deposits is 117, 498, 302, 32, and 808, respectively. This classification is used to constrain the factors controlling magmatic and hydrothermal processes, and the factors related to mineralization. Ore magmatic apatite is defined as apatite in the magmatic rocks genetically related to mineralization, whereas barren magmatic apatite refers to apatite from magmatic rocks not related to mineralization. Barren rock apatite means apatite from magmatic, sedimentary, and metamorphic rocks absent of mineralization. Hydrothermal apatite includes primary hydrothermal apatite and secondary hydrothermal altered apatite. Deposit type classification is used to discuss the main controlling factors for different types of mineralization. The deposit types include iron oxide-apatite (IOA), iron oxide-copper–gold (IOCG), porphyry, orogenic Au, skarn, and granitoidrelated deposits [\(Fig. 2\)](#page-2-0). Granitoid-related deposits have W, Mo, Cu-Pb-Zn, and Pb-Zn subtypes, whereas porphyry deposits include Cu, Cu-Au, Cu-Mo, Mo-Cu, Mo, and Au-polymetallic subtypes. Skarn deposits include Au-Co, W, and Pb-Zn subtypes. Rock type classification is used to constrain different rock-forming processes. Rock types are divided into igneous, carbonatite, sedimentary, and metamorphic rocks. Igneous rocks are further divided into acid-alkaline, acid calcium-alkaline, intermediate alkaline, intermediate calcium-alkaline, basic alkaline, basic calcium-alkaline, and ultrabasic rocks according to silicon content and alkalinity. Metamorphic rocks are divided into two subtypes: low- and

**Fig. 1.** Distribution of selected deposits and rocks. Blue color highlights regions of unmineralized rocks. The physical map of world is from M. Colpron (Geological Survey of Canada). <span id="page-2-0"></span>

**Fig. 2.** Classification of apatite by different origins.

medium-grade metamorphic rocks and high-grade metamorphic, based on the degree of metamorphism.

#### *2.2. Data preprocessing and partial least squares-discriminant analysis*

Apatite LA-ICP-MS data include censored data that are below detection limits or null ([Helsel, 2005\)](#page-21-0). Elements V, Mn Sr, Y, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, Th, and U contain less than 40 % censored values were imputed using the R-software package rob-Compositions ([Hron et al., 2010; Makvandi et al., 2016\)](#page-21-0). The centeredlog ratio (clr) method was used for data conversion to eliminate the correlation between elements inherited from concentration calculation ([Aitchison, 1982; Egozcue et al., 2003; Makvandi et al., 2016; Whitten,](#page-20-0)  [1995\)](#page-20-0). PLS-DA is carried out using the procedure similar to those described in [Huang et al. \(2019\).](#page-21-0) PLS-DA is used to distinguish magmatic versus hydrothermal apatite, barren and ore apatite, and apatite from the different deposit and rock types.

Different from the unsupervised classification method, supervised PLS-DA uses predefined data ([De Iorio et al., 2007\)](#page-20-0) to extract orthogonal components (latent variables), and construct the link between the X (N  $\times$  K) and Y (N  $\times$  M) matrices by maximizing the covariance (Brereton [and Lloyd, 2014; Eriksson et al., 2013; Wold et al., 2001](#page-20-0)):

$$
X=TP^T+E
$$

 $Y = TQ^T + F$ 

$$
T = XW^*
$$

where T ( $N \times r$ ) is the matrix containing r orthogonal PLS components (scores) and represents the common latent variable space of both X and Y. P ( $N \times r$ ) and Q ( $M \times r$ ) represent the loading matrices for X and Y. The weight matrix  $(W^*)$  is the linear regression coefficients of the X variables that best predicts Y. E and F mean the respective model residuals for X and Y.

Loadings biplots (e,g.,  $qw*_1$ ,  $qw*_2$ ) display the correlations among elements and illustrate the relationship between elements and defined groups ([Eriksson et al., 2013](#page-20-0)). Sample distribution in the score plots (e.  $g_{1}$ ,  $t_{1}$  versus  $t_{2}$ ) is controlled by the correlation among elements in the loading plot ([Eriksson et al., 2013\)](#page-20-0). The score contribution plot highlights the relative enrichment (positive score contribution) or depletion (negative score contribution) of elements in a specific group. The variable importance on the projection (VIP) plot summarizes the importance

of elements in classifying the predefined group. Elements having VIP values *>*1 are interpreted as be the most important in the classification.

Multiple steps of PLS-DA are carried out based on the origins of apatite (Fig. 2). First, PLS-DA is used to discriminate ore magmatic, barren rock, and hydrothermal apatite independent of deposit types. The discrimination between apatite from these three origins was further evaluated based on specific deposit types. Second, PLS-DA is used to distinguish different deposit types and subtypes. Third, PLS-DA is used to distinguish rock types and their subtypes.

# **3. Results**

## *3.1. Trace element composition of apatite*

[Fig. 3](#page-3-0) shows the minimum, maximum, median, and average contents of V, Mn, As, Rb, Sr, Y, Zr, Pb, Th, U, Ba, and W which have less than 60 % censored data. Ore magmatic apatite has relatively high median Mn (708 ppm) and Th (19 ppm) contents, whereas barren rock apatite has relatively high median V (16.6 ppm), Zr (4 ppm), Pb (12.5 ppm), and Ba (11 ppm) contents [\(Fig. 3a](#page-3-0)). Hydrothermal apatite has higher median As (97 ppm) and W (1.4 ppm) than ore magmatic apatite [\(Fig. 3a](#page-3-0)). [Fig. 3](#page-3-0)b shows contents of elements in magmatic and hydrothermal apatite from different deposits. Apatite from IOA deposits have relatively high median V (18.4 ppm), As (191.4 ppm), and W (3.5 ppm) contents ( $Fig. 3b$ ), whereas those from IOCG deposits have relatively high median W (2.5 ppm) and low median Th (1.2 ppm) contents [\(Fig. 3](#page-3-0)b). Apatite from skarn deposits is characterized by relatively high median Mn (1290 ppm) and low median V (0.3 ppm), As (4.5 ppm), and W (0.2 ppm) contents [\(Fig. 3](#page-3-0)b). Apatite from porphyry deposits has higher median V (21.5 ppm), Sr (544.6 ppm), and Zr (1.2 ppm) contents than others. Apatite from orogenic Au deposits is discriminated by high median Y (1190 ppm) and U (20.4 ppm) contents ( $Fig. 3b$ ). Apatite from granitoidrelated deposits has relatively high median Pb (9.2 ppm) and Th (51.9 ppm) contents ([Fig. 3b](#page-3-0)).

Apatite from igneous rocks is characterized by relatively high median V (5.4 ppm), Y (724 ppm), Pb (4.8 ppm), Th (23.3 ppm), and U  $(14.1$  ppm) contents ([Fig. 3c](#page-3-0)). Apatite from carbonatite is characterized by relatively high median V (5.3 ppm), Sr (4897 ppm), Zr (1.5 ppm), and Th (20.4 ppm) and low W (less than 0.01 ppm) contents [\(Fig. 3c](#page-3-0)). Apatite from sedimentary rocks has relatively high median As (89.3 ppm), Ba (46 ppm) and Th (0.2 ppm) contents, whereas those from metamorphic rocks have relatively high median Mn (1225 ppm) and low

<span id="page-3-0"></span>

**Fig. 3.** Box and whisker plots for LA-ICP-MS trace element data of apatite from barren rock, ore magmatic, and hydrothermal origins (a), different types of deposits (b), and different types of rocks (c) Boxes outline the 25th to 75th percentiles and whiskers extend to the minimum and maximum values. Short line within the box represents the median value, whereas circle filled by white on the whisker represents the average value. Trace element contents below the limit of detection were removed from the box and whisker plots.

V (0.2 ppm), As (4.3 ppm), Sr (131.8 ppm), Zr (0.1 ppm), and Ba (0.2 ppm) contents (Fig. 3c).

Chondrite-normalized REE spider diagrams for individual analyses and median contents of apatite are shown in [Figs. 4-6](#page-4-0). Barren rock, ore magmatic apatite, and hydrothermal apatite, show LREE-rich patterns with negative Eu anomaly [\(Fig. 4a](#page-4-0)-c). Ore magmatic and barren rock apatite have higher LREE but lower HREE than hydrothermal apatite ([Fig. 4](#page-4-0)d). Hydrothermal apatite shows stronger Eu depletion than ore magmatic and barren rock apatite [\(Fig. 4d](#page-4-0)). Ore magmatic apatite has higher LREE contents than barren rock apatite but shows similar Eu negative anomaly ([Fig. 4a](#page-4-0), b, d).

Apatite from IOA, IOCG, and orogenic Au deposits show LREE-rich patterns with negative Eu anomaly ([Fig. 5](#page-5-0)a, c). Apatite from porphyry and granitoid-related deposits also show LREE-rich pattern with

negative Eu anomaly but has higher REE contents than apatite from IOA, IOCG, and orogenic Au deposits. The Tb, Ho, Er, and Tm anomalies in apatite from granitoid-related Pb-Zn, porphyry Cu-Mo, and Mo deposits are probably due to lacking data ([Fig. 5](#page-5-0)d, e). The REE patterns of apatite from different types of porphyry deposits are similar. REE contents of apatite from granitoid-related Mo deposits are higher than those from other granitoid-related deposits ([Fig. 5](#page-5-0)d). The chondrite-normalized LREE of apatite from different porphyry deposits vary within one order of magnitude [\(Fig. 5](#page-5-0)e). Apatite from porphyry Mo-W deposits has the highest REE contents and strongest Eu negative anomaly, whereas those from porphyry Au-polymetallic deposits have the weakest negative Eu anomaly [\(Fig. 5](#page-5-0)e). Apatite from skarn W and Au-Co deposits has LREE-rich patterns, whereas that from skarn W deposits shows upconcave patterns ([Fig. 5f](#page-5-0)). The REE content of apatite from skarn W-

<span id="page-4-0"></span>

**Fig. 4.** Chondrite-normalized REE plots for median (color lines) and individual (gray lines) values of barren rock (a), ore magmatic (b), and hydrothermal apatite (c). (d) Comparison between median REE values of barren rock, ore magmatic, and hydrothermal apatite.

Cu deposits is lower than apatite from other skarn deposits ([Fig. 5f](#page-5-0)). Moreover, apatite from skarn W-Cu deposits has stronger negative Eu anomalies than that from skarn W and Au-Co deposits ([Fig. 5f](#page-5-0)).

REE patterns of most apatite from igneous rocks, carbonatite, and sedimentary rocks are LREE-rich and Eu depleted ([Fig. 6](#page-6-0)a, b, d), whereas those from metamorphic rocks are up-concave [\(Fig. 6b](#page-6-0)). Apatite from basic alkaline igneous rocks has higher REE content and stronger negative Eu anomaly than those from other igneous rocks [\(Fig. 6](#page-6-0)a). Apatite in acid alkaline, acid calcium-alkaline, intermediate alkaline, intermediate calcium-alkaline, basic alkaline, basic calcium-alkaline, and ultrabasic rocks has similar REE patterns [\(Fig. 6](#page-6-0)a). Apatite from ultrabasic igneous rocks has the lowest REE content and weakest negative Eu anomaly ([Fig. 6](#page-6-0)a). Apatite from low- and medium- grade metamorphic rocks have similar REE patterns with apatite from high grade metamorphic rocks, but the former has lower total REE contents and weaker negative Eu anomaly [\(Fig. 6b](#page-6-0)). The REE pattern of carbonatite is similar to ultrabasic rocks, which is characterized by weak negative Eu negative anomaly and HREE depletion ([Fig. 6c](#page-6-0)). Apatite from igneous rocks have higher REE contents than metamorphic and sedimentary rocks [\(Fig. 6](#page-6-0)a, c). Apatite in igneous and metamorphic rocks has negative Eu anomalies, whereas those from sedimentary rocks and carbonatite have no significant Eu anomaly [\(Fig. 6](#page-6-0)).

## *3.2. PLS-DA results of apatite composition*

## *3.2.1. Magmatic and hydrothermal apatite*

As shown in [Fig. 7a](#page-6-0), b, barren rock, ore magmatic, and hydrothermal apatite cannot be discriminated from each other in the plot of the first and second PLS-DA components. In terms of average composition, barren rock apatite is characterized by relatively high Sr, Eu, and U contents ([Fig. 7](#page-6-0)a). Ore magmatic apatite show relative enrichment of Th, Eu, La, Ce, Pr, and Nd ([Fig. 7](#page-6-0)a), whereas hydrothermal apatite is relatively rich in Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, and Y ([Fig. 7a](#page-6-0)).

# *3.2.2. Apatite from IOCG and IOA deposits grouped by ore magmatic and hydrothermal*

Ore magmatic, barren rock, and hydrothermal apatite independent of deposit types are not well separated by PLS-DA, so further PLS-DA analysis is carried out for the specific deposit types. Despite overlapping of apatite compositions of ore magmatic and hydrothermal apatite from IOCG and IOA deposits in  $t_1$ – $t_2$  [\(Fig. 8](#page-7-0)a, b). Ore magmatic apatite mainly plots on the positive side of  $t_1$  due to positive correlation with La, Ce, Pr, Nd, and U [\(Fig. 8](#page-7-0)a, b).

# *3.2.3. Apatite from granitoid-related deposits grouped by barren and ore magmatic*

Ore and barren magmatic apatite can be distinguished by PLS-DA on  $t_1$ - $t_2$  ([Fig. 9a](#page-7-0), b). Barren apatite is discriminated by the relative enrichment of U and Eu and the relative depletion of Mn, La, Ce, Pr, and Nd, in contrast to the chemical feature of ore magmatic apatite [\(Fig. 9](#page-7-0)c, d).

# *3.2.4. Apatite from porphyry deposits grouped by barren magmatic, ore magmatic, and hydrothermal apatite*

There is significant compositional overlapping among the three types of apatite ([Fig. 10](#page-8-0)a, b). Compared to the average of the dataset, barren magmatic apatite is characterized by relative enrichment of Sr and Eu

<span id="page-5-0"></span>

**Fig. 5.** Chondrite-normalized REE plots for median values of apatite from IOA (a), orogenic Au (b), IOCG (c), granitoid-related (d), porphyry (e), and skarn (f) deposits. The gray lines represent individual analyses.

([Fig. 10](#page-8-0)a). Ore magmatic apatite shows relatively high V content ([Fig. 10a](#page-8-0)), whereas hydrothermal apatite has relatively high Eu and low V contents [\(Fig. 10a](#page-8-0)).

## *3.2.5. Magmatic apatite grouped by deposit types without subtypes*

The deposit types include porphyry (Cu, Cu-Au, Cu-Mo, Mo-Cu, Mo, Au-polymetallic), granitoid-related (W, Mo, Cu-Pb-Zn, and Pb-Zn), orogenic gold, IOCG, IOA, and skarn (W, W-Cu) deposits. Magmatic apatite from porphyry deposits is separated from other types in the  $t_1-t_2$  plot due to the positive correlation with V, Sr, and Eu ([Fig. 11](#page-9-0)a, b). Magmatic apatite from granitoid-related deposits mainly plots in the positive  $t_1$  region due to the positive correlation with LREE in spite of partial overlapping with magmatic apatite from porphyry and skarn deposits ([Fig. 11](#page-9-0)c, d). Magmatic apatite from IOA deposits is separated from other deposit types in the  $t_1-t_3$  plot because of negative correlation with Mn and U ([Fig. 11](#page-9-0)c, d). The score contribution plots show that magmatic apatite from granitoid-related deposits is relatively rich in La, Ce, Pr, and Nd, and depleted in V, Sr, and Eu ([Fig. 11e](#page-9-0)), in contrast to

<span id="page-6-0"></span>

**Fig. 6.** Chondrite-normalized REE plots for median values of apatite from igneous rocks (a), metamorphic rocks (b), carbonatite (c), and sedimentary rocks (d). The gray lines represent individual analyses.

(a) Plot of qw\*<sub>1</sub> vs qw\*<sub>2</sub> (first and second loadings) showing correlation among elements and origins of apatite. (b) Plot of  $t_1$  vs  $t_2$  (first and second scores) showing the distribution of individual analyses in the latent variable space defined by  $qw^*_{1}-qw^*_{2}$  in (a). For projection of unknown samples, please see the [Appendix 3](#page-0-0).

Fig. 9. PLS-DA results of chemical composition of ore and barren magmatic apatite from granitoid-related deposits. (a) Plot of qw\*<sub>1</sub> vs qw\*<sub>2</sub> (first and second loadings) showing correlation among elements and origins of apatite. (b) Plot of  $t_1$  vs  $t_2$  (first and second scores) showing the distribution of individual analyses in the latent variable space defined by qw\*<sub>1</sub>-qw\*<sub>2</sub> in (a). (c-d) Score contribution plots of elements for different origins of granitoid-related deposits. For projection of unknown samples, please see the [Appendix 3.](#page-0-0)

*3.2.6. Hydrothermal apatite grouped by deposit types without subtypes*  Hydrothermal apatite from IOA deposits is separated from other deposit types in the  $t_1-t_2$  plot because of positive correlation with V and Sr [\(Fig. 12](#page-10-0)a, b, f). Those from IOCG, orogenic Au, porphyry Cu-Au, and

skarn (W-Cu, Au-Co) deposits cannot be discriminated in this plot. However, hydrothermal apatite from skarn deposits can be well discriminated in  $t_1-t_3$  by the positive contribution of Mn and negative contribution of V in spite of partial overlapping with orogenic Au and

<span id="page-8-0"></span>

**Fig. 10.** PLS-DA results of chemical composition of barren magmatic, ore magmatic, and hydrothermal apatite of porphyry deposits. (a) Plot of qw\*<sub>1</sub> vs qw\*<sub>2</sub> (first and second loadings) showing correlation among elements and origins of apatite. (b) Plot of  $t_1$  vs  $t_2$  (first and second scores) showing the distribution of individual analyses in the latent variable space defined by  $qw *_{1} - qw *_{2}$  in (a).

porphyry deposits [\(Fig. 12](#page-10-0) c, d, g). Hydrothermal apatite from IOCG deposits plots in the positive  $t_1$ , negative  $t_3$  region because of positive contributions of Sm, Eu, Gd, Tb, and Dy ([Fig. 12](#page-10-0)c, e). The VIP diagram shows that V, Mn, Sr, Sm, Gd, and U are important discriminant elements in the classification [\(Fig. 12h](#page-10-0)).

## *3.2.7. Magmatic apatite grouped by deposit types with subtypes*

To evaluate the classification effect of deposit subtypes, we divide granitoid-related deposits into four subtypes, skarn deposits into two subtypes, and porphyry deposits into six subtypes. Combined with undivided IOCG, IOA, and orogenic Au deposits, a total of 15 deposit types/subtypes are used for PLS-DA. Magmatic apatite from granitoidrelated W deposits is separated from other subtypes of granitoidrelated deposits by  $t_1$  because they are negatively correlated to V, Sr, and Eu [\(Fig. 13a](#page-11-0), b, h). Magmatic apatite from skarn W-Cu deposits is also separated from that from skarn W deposits by  $t_1$  because of relatively high Y, Sm, Gd, Tb, Dy, Ho, Er, Tm, Lu but low La, Ce, Pr, and Eu contents [\(Fig. 13](#page-11-0)a, b, m). Magmatic apatite from IOCG and IOA deposits mainly plots in negative  $t_3$  region due to positive correlation with Sm, Gd, Tb, Dy, Ho, Er, and negative correlation with Mn, and U [\(Fig. 13](#page-11-0)c, d, i, j). Magmatic apatite from porphyry Cu-Mo deposits plots in negative  $t_4$ region, as a result of positive correlation with Mn and negative correlation with Th ([Fig. 13e](#page-11-0), f, k). All elements except Yb are important in the classification [\(Fig. 13n](#page-11-0)).

#### *3.2.8. Hydrothermal apatite grouped by deposit types with subtypes*

The PLS-DA results of hydrothermal apatite grouped by deposit types with subtypes are similar to [Fig. 12](#page-10-0) where subtypes are not considered. Hydrothermal apatite from IOA deposits is located in negative  $t_1$  because of high V and Sr, but low U contents [\(Fig. 14a](#page-13-0), d, g). Hydrothermal apatite from skarn W-Cu deposits can be well discriminated in  $t_1-t_3$  due to the positive correlation with Mn and negative correlation with V and Sr [\(Fig. 14c](#page-13-0), d, i). Hydrothermal apatite from IOCG deposits plot in the positive  $t_1$  and negative  $t_4$  region due to positively correlated Sm, Eu, Gd, Tb, and U ([Fig. 14](#page-13-0)e, f, h). VIP plot displays that V, Mn, Sr, Sm, Eu, Gd, and U are important elements for discriminating most deposit types ([Fig. 14](#page-13-0)j).

## *3.2.9. Magmatic apatite grouped by granitoid-related deposit subtypes*

Some deposit subtypes are not well discriminated by PLS-DA when considering all the deposit types. Hence, we try to discriminate subtypes within a specific deposit type. The data of magmatic apatite define three different fields in  $t_1-t_2$ : (1) Apatite from granitoid-related W deposits plotting in the right side of  $t_1$  are discriminated by positive contributions of Y, Sm, Gd, Tb, Dy, Ho, Er, Tm, Yb and Lu ([Fig. 15a](#page-15-0), b, d, h); (2) Apatite from granitoid-related Mo deposits mainly plot in the positive side of  $t_2$ because of positive contributions of Mn and Th, but negative contributions of Sm and Gd ([Fig. 15a](#page-15-0), b, e); (3) Apatite from granitoid-related Cu-Pb-Zn and Pb-Zn deposits in the negative  $t_2$  region due to positive correlation with Sr and U ([Fig. 15a](#page-15-0), b, f, g). Apatite from granitoid-related Pb-Zn deposits plotting in the negative  $t_3$  because of positive correlation with Sr, Th, and U ([Fig. 15](#page-15-0)c, d, f, g). VIP plot shows that except V, all analyzed elements show variable importance for the studied deposit types [\(Fig. 15i](#page-15-0)).

#### *3.2.10. Magmatic apatite grouped by porphyry deposit subtypes*

Apatite from porphyry Cu-Mo and porphyry Mo deposits plots in the positive side of  $t_1$  due to relatively high Mn, Sm, and Gd and low Sr, U ([Fig. 16a](#page-16-0), b). Apatite from porphyry Cu-Au deposits clusters in the negative  $t_2$  because of positive correlation with V and U, and negative correlation with Mn, Pr, Nd, and Sm ([Fig. 16](#page-16-0)a, b, e). Apatite from porphyry Mo deposits plotting in the positive  $t_3$  is discriminated from that from porphyry Cu-Mo deposits because the former is negatively correlated with Sr and Eu [\(Fig. 16](#page-16-0)c, d, f, g). The VIP diagram shows that Mn, Sr, Sm, Eu, and Yb are important elements in the discriminant analysis ([Fig. 16](#page-16-0)h).

## *3.2.11. Apatite grouped by rock types without subtypes*

We classify the rocks hosting apatite into four groups: igneous, carbonatite, metamorphic, and sedimentary rocks. PLS-DA results show that apatite in igneous rocks and carbonatite is distinguished in  $t_1-t_2$ , whereas those from metamorphic and sedimentary rocks are overlapped ([Fig. 17a](#page-17-0), b). The score contribution plot shows that positive La, Ce, Pr, Nd, and Th, and negative Sr and Eu contributions discriminate apatite from igneous rocks ([Fig. 17c](#page-17-0)). Apatite from carbonatite is relatively rich in Sr and Eu but depleted in Tm, Lu, and U ([Fig. 17](#page-17-0)d). Apatite from metamorphic rocks shows negative contributions of La, Ce, Pr, Nd, Sm, and Th [\(Fig. 17e](#page-17-0)), whereas those from sedimentary rocks show positive Sr and Eu but negative La, Ce, Pr, and Nd contributions [\(Fig. 17f](#page-17-0)). VIP plot demonstrate that Sr, La, Ce, Pr, Nd, Eu, and Th are important discriminant elements for different types of rocks [\(Fig. 17g](#page-17-0)).

## *3.2.12. Apatite grouped by rock types with subtypes*

In order to distinguish the compositional differences of apatite

**Fig. 13.** (*continued*).

between different subtypes of igneous and metamorphic rocks, PLS-DA analysis is carried out for a total of 11 groups of rocks. Similar to the results in [Fig. 17](#page-17-0), apatite from carbonatite is separated from those from other rock types [\(Fig. 18a](#page-18-0), b). Apatite from sedimentary rocks overlaps with apatite from low- and medium-grade metamorphic rocks [\(Fig. 18](#page-18-0)a, b). Subtypes of igneous and metamorphic rocks cannot be well discriminated by PLS-DA [\(Fig. 18a](#page-18-0), b).

#### *3.2.13. Magmatic apatite grouped by subtypes of igneous rocks*

Apatite from different types of igneous rocks is not well separated by PLS-DA, when compared with carbonatite, metamorphic and sedimentary rocks ([Fig. 18](#page-18-0)). Hence, PLS-DA is used for igneous rocks to determine whether the composition and affinity of magma can be reflected by apatite chemistry. Apatite from different types of igneous rocks cannot be well discriminated in  $t_1-t_2$  [\(Fig. 19](#page-18-0)a, b). Apatite samples from intermediate alkaline igneous rocks are mainly located in the negative  $t_1$ region due to positive correlation with Sr, Eu, and V [\(Fig. 19a](#page-18-0), b).

## *3.2.14. Apatite grouped by metamorphic grades*

Apatite from high-grade and low- and medium-grade metamorphic rocks can be well discriminated in  $t_1-t_2$  with minor overlapping ([Fig. 20](#page-19-0)a, b). Apatite from low- and medium-grade metamorphic rocks is characterized by positive contributions of V and Sr and negative contributions of low La, Ce, Pr, Nd, Gd, Tb, Dy, and U, in contrast to those from high-grade metamorphic rocks [\(Fig. 20c](#page-19-0), d).

## **4. Discussion**

## *4.1. Discrimination between barren rock, ore magmatic, and hydrothermal apatite*

Barren rock, ore magmatic, and hydrothermal apatite independent of deposit types cannot be discriminated from each other ([Fig. 7b](#page-6-0)). In terms of average composition, ore apatite (including magmatic and hydrothermal) has higher contents of As, Y, U, W and lower V, Sr, Zr, Pb, and Ba than barren rock apatite [\(Fig. 3a](#page-3-0), 4d, 7b, e). Hydrothermal apatite has lower total REE and LREE, and higher U, Ba, and W contents than ore

<span id="page-13-0"></span>

**Fig. 14.** PLS-DA results of hydrothermal apatite grouped by deposit types with subtypes. Plots of first and second loadings (a), first and third loadings (c), first and fourth loadings (e) showing correlations among elements and deposit types. Plots of first and second scores (b), first and third scores (d), first and fourth scores (f) showing the distribution of individual analyses from different types of deposits in the latent variable space defined in (a), (c) and (e), respectively. (g-i) Score contribution plots of elements for the selected deposit types. (j) The VIP plot showing the importance of elements in classification. For projection of unknown samples, please see the [Appendix 3.](#page-0-0)

magmatic apatite ([Fig. 3](#page-3-0)a, 4d). The compositional overlapping between ore magmatic and hydrothermal apatite from IOCG and IOA deposits ([Fig. 8](#page-7-0)a, b) indicates no obvious chemical boundary between them. Barren magmatic, ore magmatic, and hydrothermal apatite from porphyry deposits are hardly discriminated from each other by PLS-DA ([Fig. 10](#page-8-0)). This is probably due to compositional differences between different subtypes of porphyry deposits ([Fig. 16](#page-16-0)).

Because REE are compatible with apatite crystallized from magma (D<sub>REE</sub> e<sup>nelt</sup> =  $\sim$ 1.5; Klemme and Dalpé, 2003; Prowatke and Klemme, [2006\)](#page-21-0), it is expected that REE will decrease in the residual magma and related hydrothermal solution and form hydrothermal apatite relatively depleted in REE. Moreover, REE will be metasomatically removed from the precursor magmatic or hydrothermal apatite through fluid-mineral action (e.g., dissolution-reprecipitation) to form REE-bearing minerals, such as monazite [(Ce, La, Nd, LREE) PO<sub>4</sub>] and xenotime [(Y, HREE) PO4] [\(Harlov, 2015; Harlov et al., 2002a; Harlov et al., 2002b; Harlov](#page-20-0)  [et al., 2005; Li and Zhou, 2015\)](#page-20-0), resulting in decreased REE contents in newly formed hydrothermal apatite. These expected trends are consistent with the decreased total REE contents from magmatic to hydrothermal apatite. The transition from magmatic apatite to hydrothermal fluorapatite is characterized by an overall increase in HREE concentrations, likely because fluids preferentially combine with LREE at elevated temperatures, resulting in decoupling of LREE and HREE [\(Mercer et al.,](#page-21-0)  [2020; Su et al., 2021](#page-21-0)). Experience and field works demonstrate that Sr and Mn are fluid mobile elements ([Reed et al., 2000; Simon et al., 2007;](#page-21-0)  [Williams-Jones and Heinrich, 2005\)](#page-21-0), and are enriched in hydrothermal apatite ([La Cruz et al., 2019](#page-21-0)). The relative enrichment of U and depletion of Th in hydrothermal apatite is consistent with that hydrothermal apatite commonly has higher U/Th ratios than magmatic apatite in IOA deposits [\(Krneta et al., 2017a; Zeng et al., 2016](#page-21-0)). Therefore, the PLS-DA result is consistent with the natural and experimental observation of compositional variations between magmatic and hydrothermal apatite.

Barren magmatic and ore magmatic apatite from granitoid-related deposits are well separated by PLS-DA ([Fig. 9a](#page-7-0), b), due to relatively

high V, Sr, Eu, Th, and U for the former and relatively high Mn, La, Ce, Pr, and Nd contents for the latter ([Fig. 9](#page-7-0)). The relative enrichment of Sr and depletion of Mn in barren magmatic apatite likely reflect lower degree of differentiation and more aluminous magma [\(Chu et al., 2009](#page-20-0)).

# *4.2. Discrimination of magmatic and hydrothermal apatite from different types of deposits*

REE patterns of magmatic apatite commonly exhibit negative or no Eu anomalies [\(Fig. 6\)](#page-6-0), which are related to the magma oxygen fugacity and feldspar fractionation [\(Bea and Montero, 1999](#page-20-0)). However, positive Eu anomalies of magmatic apatite cannot be due to crystal fractionation and likely inherited from magma source [\(Chu et al., 2009\)](#page-20-0).

Magmatic apatite from granitoid-related, IOA, and granitoid-related deposits can be discriminated but those of skarn, IOCG, and orogenic Au deposits plot in the center of  $t_1-t_2$  and  $t_1-t_3$  ([Fig. 11](#page-9-0) a-d). Magmatic apatite from IOA deposits is discriminated by relatively high Nd, Sm, Gd, Tb, Dy, and low Mn and U contents ([Fig. 11](#page-9-0)f). Low Mn in apatite from IOA deposits is probably due to crystallization of Mn-compatible magnetite microlites, resulting in the relative depletion of Mn in associated apatite [\(Knipping et al., 2015\)](#page-21-0). Monazite is the main mineral of IOA deposits rich in LREE, and the crystallization of monazite decreases with increasing ASI ([Adlakha et al., 2018; Montel, 1993\)](#page-20-0). Therefore, high HREE contents in IOA magmatic apatite are probably related to peraluminous magmas. Stronger negative Eu anomaly of apatite from IOA deposits ([Fig. 6](#page-6-0)a) is consistent with the lower oxidation state of IOA ore system [\(Mercer et al., 2020](#page-21-0)). Magmatic apatite from porphyry deposits is discriminated by relatively high V, Sr, and Eu contents ([Fig. 11](#page-9-0)a, b, g). Relatively high Sr in apatite from porphyry deposits is possibly due to the adakite-like chemical feature of studied porphyry characterized by high Sr contents.

The relatively low Mn contents in magmatic apatite from granitoidrelated Cu-Pb-Zn deposits [\(Fig. 15](#page-15-0)g) are related to relatively high oxygen fugacity of the host magma ([Ding et al., 2015; Miles et al., 2014;](#page-20-0) 

<span id="page-15-0"></span>

**Fig. 15.** PLS-DA results of magmatic apatite grouped by subtypes of granitoid-related deposits. <span id="page-17-0"></span>

**Fig. 17.** PLS-DA results of apatite grouped by rock types without subtypes. Plots of first and second loadings (a) showing correlations among elements and deposit types. Plots of first and second scores (b) showing the distribution of individual analyses from different types of rocks in the latent variable space defined in (a). (c-f) Score contribution plots of elements for the selected rock types. (g) The VIP plot showing the importance of elements in classification. For projection of unknown samples, please see the [Appendix 3.](#page-0-0)

[Yang et al., 2018\)](#page-20-0). Meanwhile, apatite from granitoid-related Cu-Pb-Zn deposit is distinguished by higher concentration of Sr in comparison to granitoid-related Mo deposit possibly reflecting more mafic magma sources for the former ([Belousova et al., 2002; Zafar et al., 2020](#page-20-0)). Magmatic apatite from Mo-bearing granites is rich in Th ([Fig. 15e](#page-15-0)), likely because the melting of sediments increases the Th content in the magma source ([Adlakha et al., 2018; Ding et al., 2015\)](#page-20-0).

The relatively high V and low Mn and Nd contents characterize magmatic apatite from porphyry Cu-Au deposits [\(Fig. 16](#page-16-0)e). The Nd depletion is consistent with that subduction-related host rocks have negative anomalies for high field strength elements like Nd ([Cao et al.,](#page-20-0)  [2022\)](#page-20-0). The relatively low oxygen fugacity of the magma possibly explains the relatively high Mn and low Eu in magmatic apatite from porphyry Cu-Mo and Mo deposits [\(Cao et al., 2012](#page-20-0)). The more evolved

magma for Mo-mineralization of porphyry deposits accounts for the relatively high contents of Pr, Nd, and Sm and low Sr in magmatic apatite from porphyry Cu-Mo and Cu deposits [\(Cao et al., 2012; Chen](#page-20-0)  [and Zhang, 2018\)](#page-20-0).

Hydrothermal apatite from IOCG, IOA, and skarn deposits can be distinguished from other deposit types ([Figs. 12 and 14\)](#page-10-0). Hydrothermal apatite from IOCG deposits has higher U and REE contents than those from IOA deposits ([Fig. 3](#page-3-0)b, [5](#page-5-0)a, c, and [12](#page-10-0)), because lower temperature of IOCG deposit cause precipitation of REE in Cl-rich fluid [\(Williams-Jones](#page-21-0)  [and Heinrich, 2005\)](#page-21-0). Relatively low Gd and Tb in hydrothermal apatite from skarn deposits possibly due to the fractionation of Gd and Tb by amphibole, because amphibole preferentially incorporates medium REE over other REE [\(Adlakha et al., 2018](#page-20-0)).

<span id="page-18-0"></span>

**Fig. 18.** PLS-DA results of apatite grouped by rock types with subtypes. Plots of first and second loadings (a) showing correlations among elements and deposit types. For projection of unknown samples, please see [Appendix 3.](#page-0-0)

**Fig. 19.** PLS-DA results of magmatic apatite grouped by igneous rock types. Plots of first and second loadings (a) showing correlations among elements and deposit types. Plots of first and second scores (b) showing the distribution of individual analyses from different types of rock in the latent variable space defined in (a).

## *4.3. Discrimination apatite from different types of rocks*

Experimental studies have demonstrated that partition coefficients of halogens ([Doherty et al., 2014; Konzett et al., 2012; Kusebauch et al.,](#page-20-0)  [2015; Mathez and Webster, 2005; McCubbin et al., 2015; Webster et al.,](#page-20-0)  [2017; Webster et al., 2009\)](#page-20-0) and trace elements [\(Klemme and Dalp](#page-21-0)é, [2003; Li and Hermann, 2017; Prowatke and Klemme, 2006; Watson and](#page-21-0)  [Green, 1981\)](#page-21-0) between melts and apatite are strongly influenced by melt chemistry. Carbonatitic melts are characterized by high Sr, Ba, and REE abundances ([Jones et al., 2013\)](#page-21-0). Most trace elements like REE, Sr, Y, Th, and U show decreased apatite-melt partition coefficients with increasing silica and decreasing Ca and P in melts [\(Klemme and Dalp](#page-21-0)é, 2003). Because carbonatitic melts are commonly formed from sediments melting during subduction, the melts are relatively rich in P because sediments contain large amounts of P ([Plank and Langmuir 1998\)](#page-21-0). The more Ca-enriched and Si-depleted carbonatitic magma thus explains the

<span id="page-19-0"></span>

**Fig. 20.** PLS-DA results of apatite grouped by metamorphic grades. Plots of first and second loadings (a) showing correlations among elements and deposit types. Plots of first and second scores (b) showing the distribution of individual analyses from different metamorphic grades in the latent variable space defined in (a). (c-d) Score contribution plots of elements. For the projection of unknown samples, please see [Appendix 3](#page-0-0).

higher Sr and REE contents in apatite from carbonatite ([Fig. 17](#page-17-0)d). The REE contents of apatite from sedimentary rocks are lower than igneous rocks and carbonatite [\(Fig. 5](#page-5-0)), because surface waters have relatively low concentration of REE [\(Bea, 1996; Joosu et al., 2016\)](#page-20-0).

Apatite from igneous rocks with different compositions is hard to be discriminated by PLS-DA [\(Figs. 18 and 19](#page-18-0)). It is expected there is a regular variation of elements in apatite with ultrabasic to acid based on experimental studies (Klemme and Dalpé, 2003; Prowatke and Klemme, [2006\)](#page-21-0). However, no regular changes in apatite chemistry of ultrabasic to acid and alkaline to calcium alkaline of host rocks were observed. This possibly reflects the different magma sources for these igneous rocks. Apatite from metamorphic rocks can be discriminated by the metamorphic grades (Fig. 20). Higher REE contents in apatite with higher grade of metamorphism are possibly due to the breakdown of hornblende, allanite, and titanite to release REE [\(Bea and Montero, 1999;](#page-20-0)  [Bingen et al., 1996\)](#page-20-0).

#### *4.4. Implication for mineral exploration*

Source discrimination is one of the important steps for using indicator minerals in mineral exploration. Previous studies commonly used apatite chemistry to determine the mineralization potential of rocks in a specific region [\(Cao et al., 2012; Krneta et al., 2017b; Mukherjee et al.,](#page-20-0)  [2017; Pan et al., 2016](#page-20-0)), but whether these rules can be used to other regions remain unknown. [Mao et al. \(2016\) and O](#page-21-0)'Sullivan et al. (2020) use a larger dataset and considered that discriminant projection analysis (DPA) and principal components analysis (PCA) methods are useful in

discriminating apatite from deposit and rock types. This study proposes a new method to discriminate apatite with different origins by multiple steps of PLS-DA ([Fig. 21\)](#page-20-0). First, [Figs. 11 to 14](#page-9-0) are used to discriminate deposit types. Second, [Figs. 8-10](#page-7-0) are used to discriminate barren magmatic, ore magmatic, and hydrothermal apatite, and [Figs. 15 and 16](#page-15-0)  are used to discriminate subtypes of granitoid-related and porphyry deposits, respectively. In addition to deposit type discrimination, rock type discrimination can be carried out at the same time. [Figs. 17 and 18](#page-17-0)  are used to discriminate rock types. Fig. 20 is further used to distinguish the metamorphic grades of rocks. By combining the above results, the origin of apatite can be determined.

# **5. Conclusions**

Partial least squares-discriminant analysis is used to classify apatite from different origins, magmatic vs hydrothermal, barren vs mineralization, deposit types, and rock types. Barren rock, ore magmatic, and hydrothermal apatite independent of deposit types cannot be separated, however, for specific deposit types (e.g., granitoid-related deposits), these three origins of apatite can be partly separated. Magmatic apatite from granitoid-related, porphyry, and IOA deposits, and IOA deposits can be discriminated from IOCG, skarn, and orogenic Au deposits, whereas hydrothermal apatite from IOCG, IOA and skarn deposits can be distinguished from orogenic and porphyry deposits. Subtypes of granitoid-related, porphyry, and skarn deposits are also further classified. Magmatic apatite from granitoid-related Mo, Pb-Zn, Cu-Pb-Zn, and W deposits is well separated. Magmatic apatite from porphyry Cu-Au,

<span id="page-20-0"></span>

**Fig. 21.** The flowchart to identify apatite with unknown origins.

Mo, and Cu-Mo deposits are distinguished from other porphyry deposit subtypes. Apatite from igneous rocks, carbonatite, metamorphic rocks, and sedimentary rocks is well discriminated. Different compositions of igneous rocks (from ultrabasic to acidic, alkaline vs calcium-alkaline) cannot be separated. High-grade metamorphic rocks can be discriminated from low- and medium-grade metamorphic rocks. This study demonstrates that apatite chemistry combined with PLS-DA is useful to discriminate apatite with different origins. A flowchart for discriminating apatite with unknown origins is also proposed and can be used in mineral exploration.
